Prediction of time series by statistical learning: general losses and fast rates

Abstract
We establish rates of convergences in statistical learning for time series forecasting. Using the PAC-Bayesian approach, slow rates of convergence $\sqrt{n/d}$ for the Gibbs estimator under the absolute loss were given in a previous work [7], where $n$ is the sample size and $d$ the dimension of the set of predictors. Under the same weak dependence conditions, we extend this result to any convex Lipschitz loss function. We also identify a condition on the parameter space that ensures similar rates for the classical penalized ERM procedure. We apply this method for quantile forecasting of the French GDP. Under additional conditions on the loss functions (satisfied by the quadratic loss function) and for uniformly mixing processes, we prove that the Gibbs estimator actually achieves fast rates of convergence $d/n$. We discuss the optimality of these different rates pointing out references to lower bounds when they are available. In particular, these results bring a generalization the results of [29] on sparse regression estimation to some autoregression.

1. Introduction
Time series forecasting is a fundamental subject in the statistical processes literature. The parametric approach contains a wide range of models associated with efficient estimation and prediction procedures [36]. Classical parametric models include linear processes such as ARMA models [10]. More recently, non-linear processes such as stochastic volatility and ARCH models received a lot of attention in financial applications - see, among others, the Nobel awarded paper [33], and [34] for a survey of more recent advances. However, parametric assumptions rarely hold on data. Assuming that the observations satisfy a model can bias the prediction and highly underevaluate the risks, see the polemical but highly informative discussion in [61].

In the last few years, several universal approaches emerged from various fields such as non-parametric statistics, machine learning, computer science and game theory. These approaches share some common features: the aim is to build a procedure that predicts the time series as well as the best predictor in a restricted set of initial predictors $\Theta$, without
any parametric assumption on the distribution of the observed time series. Note however that the set of predictors can be inspired by different parametric or non-parametric statistical models. We can distinguish two classes in these approaches, with different quantifications of the objective, and different terminologies:

- in the “batch” approach, the family of predictors is sometimes referred to as “model” or “set of concepts”. All the observations are given at the same time; the sample \(X_1, \ldots, X_n\) is modelled as random. Some hypotheses like mixing or weak dependence are required: see \([7, 21, 37, 47, 49, 55, 56, 66, 67]\).

- in the “online” approach, predictors are usually referred to as “experts”. At each date \(t\), a prediction of the future realization \(X_{t+1}\) is based on the previous observations \(X_1, \ldots, X_t\), the objective being to minimize the cumulative prediction loss, see \([18, 59]\) for an introduction. The observation are often modeled as deterministic in this context, the problem is then referred as “prediction of individual sequences” - but a probabilistic model is also used sometimes \([13]\).

In both settings, one is usually able to predict the time series as well as the best expert in the set of experts \(\Theta\), the complexity term classification \([46, 60]\), but were later extended to other problems \([3, 4, 16, 17, 28, 40, 57]\). In PAC-Bayesian inequalities, our main results are based on PAC-Bayesian oracle inequalities. This type of results were first established for supervised classification \([46, 60]\), but were later extended to other problems \([3, 4, 16, 17, 28, 40, 57]\). In PAC-Bayesian inequalities, the complexity term \(d(\Theta)\) is defined thanks to a prior distribution on the set \(\Theta\).

The method proposed in \([7]\) is a two-step procedure: first, a set of randomized estimators is drawn, then, one of them is selected by the minimization of a penalized criterion. In this paper, we consider the one step Gibbs estimator introduced in \([16]\) (the Gibbs procedure is related with online approaches like the weighted majority algorithm of \([44, 64]\)). The advantage of this procedure is that it is potentially computationally more efficient when the number of submodels \(M\) is very large, this situation is thoroughly discussed in \([3, 29]\) in the context of i.i.d. observations. We discuss the applicability of the procedure for various time series. Also, under additional assumptions on the model, we prove that the classical Empirical Risk Minimization (ERM) procedure can be used instead of the Gibbs estimator. On the contrary to the Gibbs estimator, there is no tuning parameter for the ERM, so this is a very favorable situation. We finally prove that, for a wide family of loss functions including the quadratic loss, the Gibbs estimator reaches the optimal rate \(\Delta(n, \epsilon) \approx d(n, \epsilon)/n\) under \(\phi\)-mixing assumptions. To our knowledge, this is the first time such a result is obtained in this setting. Note however that \([1, 22]\) proves similar results in the online setting, and proves that it is possible to extend the results to the batch setting under \(\phi\)-mixing assumptions. However, their assumptions on the mixing coefficients is much stronger (our theorem only require summability while their result require exponential decay of the coefficients).

Our main results are based on PAC-Bayesian oracle inequalities. This type of results were first established for supervised classification \([46, 60]\), but were later extended to other problems \([3, 4, 16, 17, 28, 40, 57]\). In PAC-Bayesian inequalities, the complexity term \(d = d(\Theta)\) is defined thanks to a prior distribution on the set \(\Theta\).

The paper is organized as follows: Section 2 provides notations used in the whole paper. We give a definition of the Gibbs and the ERM estimators in Section 2.2. The main hypotheses necessary to prove theoretical results on these estimators are provided in Section 3. We give examples of inequalities of the form (1) for classical sets of predictors \(\Theta\) in Section 4. When possible, we also prove some results on the ERM in these settings. These results only require a general weak-dependence type assumption on the time series to forecast. We then study fast rates under a stronger \(\phi\)-mixing assumptions of \([38]\) in Section 5. As a special case, we generalize the results of \([3, 29, 35]\) on sparse regression estimation to the case of autoregression. In Section 6 we provide an application to French GDP forecasting. A short simulation study is provided in Section 7. Finally, the proofs of all the theorems are given in Appendices 9 and 10.

2. Preliminaries

2.1. Notations

Let \(X_1, \ldots, X_n\) denote the observations at time \(t \in \{1, \ldots, n\}\) of a time series \(X = (X_t)_{t \in \mathbb{Z}}\) defined on \((\Omega, \mathcal{A}, \mathbb{P})\). We assume that this series takes values in \(\mathbb{R}^d\). We denote \(|| \cdot ||\) and \(|| \cdot ||_1\) respectively the Euclidean and the \(\ell^1\) norms.
of \( \mathbb{R}^p \), \( p \geq 1 \). We denote \( k \) an integer \( k(n) \in \{1, \ldots, n\} \) that might depend on \( n \). We consider a family of predictors \( \{f_\theta : (\mathbb{R}^p)^k \to \mathbb{R}^p, \theta \in \Theta \} \). For any parameter \( \theta \) and any time \( t \), \( f_\theta(X_{t-1}, \ldots, X_{t-k}) \) is the prediction of \( X_t \) returned by the predictor \( \theta \) when given \( (X_{t-1}, \ldots, X_{t-k}) \). For the sake of shortness, we use the notation:

\[
\hat{X}_t^\theta := f_\theta(X_{t-1}, \ldots, X_{t-k}).
\]

Notice that no assumptions on \( k \) will be used on the paper, the choice of \( k \) is determined by the context. For example, if \( X \) is a Markov process, it makes sense to fix \( k = 1 \). In a completely agnostic setting, one might consider larger \( k \). We assume that \( \Theta \) is a subset of a vector space and that \( \theta \to f_\theta \) is linear. We consider a loss function \( \ell : \mathbb{R}^p \times \mathbb{R}^p \to \mathbb{R}_+ \) that measures a distance between the forecast and the actual realization of the series. Assumptions on \( \ell \) will be given in Section 3.

**Definition 1.**
For any \( \theta \in \Theta \) we define the prediction risk as

\[
R(\theta) = \mathbb{E}[\ell(\hat{X}_t^\theta, X_t)].
\]

The main assumption on the time series \( X \) is that the risk function \( R(\theta) \) does effectively not depend on \( t \). This is true for any strongly stationary time series. Using the statistics terminology, note that we may want to include parametric set of predictors as well as non-parametric ones (i.e. respectively finite dimensional and infinite dimensional \( \Theta \)). Let us mention classical parametric and non-parametric families of predictors:

**Example 1.**
Define the AR predictors with \( j \) parameters as

\[
f_\theta(X_{t-1}, \ldots, X_{t-k}) = \theta_0 + \sum_{i=1}^{j-1} \theta_i X_{t-i}
\]

for \( \theta = (\theta_0, \theta_1, \ldots, \theta_{j-1}) \in \Theta \subset \mathbb{R}^j \).

In order to deal with non-parametric settings, we will also use a model-selection type notation. By this, we mean that we will consider many possible models \( \Theta_1, \ldots, \Theta_M \), coming for example from different levels of approximation, and finally consider \( \Theta = \bigcup_{j=1}^M \Theta_j \) (see e.g. Chapter 1 in [45]). Note that \( M \) can be any integer and might depend on \( n \).

**Example 2.**
Consider non-parametric auto-regressive predictors

\[
f_\theta(X_{t-1}, \ldots, X_{t-k}) = \sum_{j=1}^{j} \theta_j \varphi_j(X_{t-1}, \ldots, X_{t-k})
\]

where \( \theta = (\theta_1, \ldots, \theta_j) \in \Theta_j \subset \mathbb{R}^j \) and \( (\varphi_j)_{j=0}^\infty \) is a dictionary of functions \( (\mathbb{R}^p)^k \to \mathbb{R}^p \) (following e.g. [29]) by dictionary of function we actually mean any family of functions, for example the Fourier basis, a wavelet basis, splines, polynomials...). It is well-known that a small \( j \) will lead to poor approximations properties of \( \Theta_j \) (large bias), while a large \( j \) leads to a huge variability in the estimation. In this situation, our main results allow the case \( M = n \) and provide an estimator on \( \Theta = \bigcup_{j=1}^M \Theta_j \) that will achieve the optimal balance between bias and variance.
2.2. The ERM and Gibbs estimators

Consider that $\Theta = \bigcup_{j=1}^M \Theta_j$. As the objective is to minimize the risk $R(\cdot)$, we use the empirical risk $r_n(\cdot)$ as an estimator of $R(\cdot)$.

**Definition 2.**
For any $\theta \in \Theta$, $r_n(\theta) = \frac{1}{n} \sum_{i=k+1}^n \ell \left( \hat{X}_i^\theta, X_i \right)$.

**Definition 3 (ERM).**
For any $1 \leq j \leq M$, the ERM in $\Theta_j$ is defined by

$$\hat{\theta}_j^{ERM} \in \arg \min_{\theta_j \in \Theta_j} r_n(\theta_j).$$

We will denote $\hat{\theta}_j^{ERM}$ the ERM defined on the entire parameter space $\Theta$. It is well known that if $\Theta$ is a high dimensional space then the ERM suffers overfitting. In such cases, we reduce the dimension of the statistical problem by selecting a model through a penalization procedure. The resulting procedure is known under the name SRM (Structural Risk Minimization) [63], or penalized risk minimization [12].

**Definition 4 (SRM).**
Define the two steps estimator as $\hat{\theta}_j^{ERM}$ where $j$ minimizes the function of $j$

$$r_n(\hat{\theta}_j^{ERM}) + \text{pen}_j$$

for some penalties $\text{pen}_j > 0, 1 \leq j \leq M$.

In some models, risk bounds on the ERM are not available. In order to deal with these models, we introduce another estimator: the Gibbs estimator. Let $\mathcal{T}$ be a $\sigma$-algebra on $\Theta$ and $\mathcal{M}^1(\Theta)$ denote the set of all probability measures on $(\Theta, \mathcal{T})$. The Gibbs estimator depends on a fixed probability measure $\pi \in \mathcal{M}^1(\Theta)$ called the prior. However, $\pi$ should not necessarily be seen as a Bayesian prior: as in [17], the prior will be used to define a measure of the complexity of $\Theta$ (in the same way than the VC dimension of a set [63] measures its complexity).

**Definition 5 (Gibbs estimator).**
Define the Gibbs estimator with inverse temperature $\lambda > 0$ as

$$\hat{\theta}_j = \int_\Theta \theta \hat{\rho}_j(d\theta), \quad \text{where } \hat{\rho}_j(d\theta) = \frac{e^{-\frac{1}{n} \ell(\theta)}}{\int e^{-\frac{1}{n} \ell(\theta)} \pi(d\theta)}. $$

The choice of $\pi$ and $\lambda$ is discussed in Section 4. Consider the model-selection set-up $\Theta = \bigcup_{j=1}^M \Theta_j$ for disjoints $\Theta_j$. In [7], the following penalization procedure was studied: first, calculate a Gibbs estimator $\hat{\theta}_{j,j}$ in each $\Theta_j$, then, choose one of them based on a penalized minimization criterion similar to the one in Definition 4. In this paper, even in the model selection setup, we will define a probability distribution on the whole space $\Theta = \bigcup_{j=1}^M \Theta_j$ and use Definition 5 to define the Gibbs estimator on $\Theta$. 

68
2.3. Oracle inequalities

Consider some parameter space $\Theta$ that is the union of $M$ disjoint sets $\Theta = \bigcup_{j=1}^{M} \Theta_j$. Our results assert that the risk of the estimators are close to the best possible risk up to a remainder term with high probability $1 - \varepsilon$. The rate at which the remainder term tends to zero with $n$ is called the rate of convergence. We introduce the notation $\mathcal{B}_j$ and $\mathcal{B}$ with

$$R(\mathcal{B}_j) = \inf_{\theta \in \mathcal{B}_j} R(\theta) \text{ and } R(\mathcal{B}) = \inf_{\theta \in \mathcal{B}} R(\theta)$$

we assume that these minimizers exists, they don’t need to be unique; when they don’t exist, we can replace these by approximate minimizers. We want to prove that the ERM or Gibbs estimators satisfy, for any $\varepsilon \in (0, 1)$ and any $n \geq 0$, the so-called oracle inequality:

$$\Pr \left( R(\hat{\theta}) \leq \min_{1 \leq j \leq M} \left[ R(\mathcal{B}_j) + \Delta_j(n, \varepsilon) \right] \right) \geq 1 - \varepsilon \quad (2)$$

where the error terms $\Delta_j(n, \varepsilon) \to 0$ as $n \to \infty$ (we will also consider oracle inequalities when $M = 1$, in this case, we will use the notation $\Delta_j(n, \varepsilon)$ instead of $\Delta_1(n, \varepsilon)$). Slow (resp. fast) rates of convergence correspond to $\Delta_j(n, \varepsilon) = O(n^{-1/2})$ (resp. $O(n^{-1})$) when $\varepsilon > 0$ is fixed for all $1 \leq j \leq M$. It is also important to estimate the increase of the error terms $\Delta_j(n, \varepsilon)$ when $\varepsilon \to 0$. Here it is proportional to $\log(\varepsilon^{-1})$, that corresponds to an exponential tail behavior of the risk.

To establish oracle inequalities, we require some assumptions discussed in the next section.

3. Main assumptions

We prove in Section 4 oracle inequalities under assumptions of three different types. First, assumptions Bound(\mathcal{B}), WeakDep(\mathcal{C}) and PhiMix(\mathcal{C}) hold on the dependence and boundedness of the time series. In practice, we cannot know whether these assumptions are satisfied on data. However, these assumptions are satisfied for many classical time series as shown in [23, 26].

Second, assumptions LipLoss(\mathcal{K}), Lip(\mathcal{L}), Dim(d, D) and L1(\mathcal{P}) hold respectively on the loss function $\ell$, the predictors $\hat{X}_j^{\theta}$ and the parameter spaces $\Theta_j$. These assumptions can be checked in practice as the statistician know the loss function and the predictors.

Finally, the assumption Margin(\mathcal{K}) involve both the observed time series and the loss function $\ell$. As in the iid case, it is only required to prove oracle inequalities with fast rates.

3.1. Assumptions on the time series

Assumption Bound(\mathcal{B}), $B > 0$: for any $t > 0$ we have $\|X_t\| \leq B$ almost surely.

It is possible to extend some of the results in this paper to unbounded time series using the truncation technique developed in [7]. The price to pay is an increased complexity in the bounds, so, for the sake of simplicity, we only deal with bounded series in this paper.

Assumption WeakDep(\mathcal{C}) is about the $\theta_{\infty, \ell}(1)$-weak dependence coefficients of [23, 53].

**Definition 6.**

For any $k > 0$, define the $\theta_{\infty, \ell}(1)$-weak dependence coefficients of a bounded stationary sequence $(X_t)$ by the relation

$$\theta_{\infty, \ell}(1) := \sup_{t \in \Lambda_1^k, 0 < j_1 < \cdots < j_k} \left\| \mathbb{E} \left[ f(X_{j_1}, \ldots, X_{j_k}) | X_t, t \leq 0 \right] - \mathbb{E} \left[ f(X_{j_1}, \ldots, X_{j_k}) \right] \right\|_{\infty},$$

$\|V\|_{\infty}$ refers to the essential supremum of the random variable $\|V\|$ where $V$ is a random vector in $\mathbb{R}^k$ where $\Lambda_1^k$ is the set of $1$-Lipshitz functions of $k$ variables

$$\Lambda_1^k = \left\{ f : (\mathbb{R}^k)^k \to \mathbb{R}, \quad \frac{|f(u_1, \ldots, u_k) - f(u'_1, \ldots, u'_k)|}{\sum_{j=1}^{k} \|u_j - u'_j\|} \leq 1 \right\}.$$
The sequence \( \{\theta_{\omega,k}(1)\}_{k>0} \) is non decreasing with \( k \). The idea is that as soon as \( X_t \) behaves “almost independently” from \( X_0, X_1, \ldots \) then \( \theta_{\omega,k}(1) - \theta_{\omega,k-1}(1) \) becomes negligible. Actually, it is known that for many classical models of stationary time series, the sequence is upper bounded, see [23] for details.

Assumption WeakDep(C), \( C > 0 \): \( \theta_{\omega,k}(1) \leq C \) for any \( k > 0 \).

**Example 3.**
Examples of processes satisfying WeakDep(C) and Bound(B) are provided in [7, 23, 32]. It includes Bernoulli shifts \( X_t = H(\xi_t, \xi_{t-1}, \ldots) \) where the \( \xi_t \) are iid, \( ||\xi_0|| \leq b \) and \( H \) satisfies a Lipschitz condition:

\[
||H(v_1, v_2, \ldots) - H(v'_1, v'_2, \ldots)|| \leq \sum_{j=0}^{\infty} a_j ||v_j - v'_j|| \text{ with } \sum_{j=0}^{\infty} j a_j < \infty.
\]

Then \( (X_t) \) is bounded by \( B = H(0, 0, \ldots) + bC \) and satisfies WeakDep(C) with \( C = \sum_{j=0}^{\infty} j a_j \). In particular, solutions of linear ARMA models with bounded innovations satisfy WeakDep(C), as well a large class of Markov models and non-linear ARCH models, see [32] p. 2003-2004.

In order to prove the last rates oracle inequalities, a more restrictive dependence condition is assumed. It holds on the uniform mixing coefficients introduced by [38].

**Definition 7.**
The \( \phi \)-mixing coefficients of the stationary sequence \( (X_t) \) with distribution \( \mathbb{P} \) are defined as

\[
\phi_r = \sup_{\{A, B\} \subseteq I, \sigma(X_r, t \in I) \cap \sigma(X_r, t \in A)} |\mathbb{P}(B|A) - \mathbb{P}(B)|
\]

where \( \sigma(X_t, t \in I) \) is the \( \sigma \)-algebra generated by the set of random variables \( \{X_t, t \in I\} \).

Assumption PhiMix(C), \( C > 0 \): \( 1 + \sum_{r=1}^{\infty} \sqrt{\phi_r} \leq C \).

This assumption appears to be more restrictive than WeakDep(C) for bounded time series:

**Proposition 1 ([53]).**
Let \( (X_t) \) be any time series that satisfies Bound(B) and PhiMix(C). Then it also satisfies WeakDep(C|B).

(This is a direct consequence of the last inequality in the proof of Corollaire 1 p. 907 in [53]).

3.2. Assumptions on the loss function

Assumption LipLoss(K), \( K > 0 \): the loss function \( \ell \) is given by \( \ell(x, x') = g(x - x') \) for some convex \( K \)-Lipschitz function \( g \) such that \( g(0) = 0 \) and \( g \geq 0 \).

**Example 4.**
A classical example in statistics is given by \( \ell(x, x') = ||x - x'|| \), it is the loss used in [7]; this loss is the absolute loss in the case of univariate time series. It satisfies LipLoss(K) with \( K = 1 \). In [47, 49], the loss function used is the quadratic loss \( \ell(x, x') = ||x - x'||^2 \). When Bound(B) is satisfied, the quadratic loss satisfies LipLoss(2B).
Example 5.
The class of quantile loss functions introduced in [41] is given by

$$\ell_t(x, y) = \begin{cases} \tau (x - y), & \text{if } x - y > 0 \\ -(1 - \tau)(x - y), & \text{otherwise} \end{cases}$$

where $\tau \in (0, 1)$ and $x, y \in \mathbb{R}$. The risk minimizer of $t \mapsto \mathbb{E}(\ell_t(V - t))$ is the quantile of order $\tau$ of the random variable $V$. Choosing this loss function one can deal with rare events and build confidence intervals [9, 13, 42]. In this case, $\text{LipLoss}(K)$ is satisfied with $K = \max(1, 1 - \tau) \leq 1$.

Assumption $\text{Lip}(L_j)$, $L_j > 0$: for any $\theta \in \Theta_j$ there are coefficients $a_j(\theta)$ for $1 \leq j \leq k$ such that, for any $x_1, \ldots, x_k$ and $y_1, \ldots, y_k$,

$$\|f_\theta(x_1, \ldots, x_k) - f_\theta(y_1, \ldots, y_k)\| \leq \sum_{j=1}^k a_j(\theta) \|x_j - y_j\|,$$

with $\sum_{j=1}^k a_j(\theta) \leq L_j$.

To define the Gibbs estimator we set a prior measure $\pi$ on the parameter space $\Theta$. The complexity of the parameter space is determined by the growth of the volume of sets around the oracle $\overline{B}_j$:

Assumption $\text{Dim}(d_j, D_j)$: there are constants $d_j = d(\Theta_j, \pi_j)$ and $D_j = D(\Theta_j, \pi_j)$ satisfying

$$\forall \delta > 0, \quad \pi_j(\{\theta : R(\theta) - R(\overline{B}) < \delta\}) \leq \left(\frac{\delta}{D_j}\right)^{d_j}.$$

This assumption basically states that the prior gives enough weight to the sets $\{\theta : R(\theta) - R(\overline{B}) < \delta\}$. As discussed in [7, 17], it holds for reasonable priors when $\Theta_j$ is a compact set in a finite dimensional space with $d_j$ depending on the dimension and $D_j$ depending on the diameter of $\Theta_j$. In the case of the ERM, we need a more restrictive assumption that states that we can compare the set $\{\theta : R(\theta) - R(\overline{B}) < \delta\}$ to some $\ell^1$ ball in $\Theta$.

Assumption $\text{L1}(\Psi)$, $\psi > 0$: $\|\hat{\lambda}_1^\delta - \hat{\lambda}_1^\theta\| \leq \psi \|\theta_1 - \theta_2\|$, a.s. for all $(\theta_1, \theta_2) \in \Theta^2$.

3.3. Margin assumption

Finally, for fast rates oracle inequalities, an additional assumption on the loss function $\ell$ is required. In the iid case, such a condition is also required. It is called Margin assumption or Bernstein hypothesis.

Assumption $\text{Margin}(K)$, $K > 0$: for any $\theta \in \Theta$,

$$\mathbb{E}\left[\left(\ell\left(X_{q+1}, f_\theta(X_q, \ldots, X_1)\right) - \ell\left(X_{q+1}, f_{\overline{\theta}}(X_q, \ldots, X_1)\right)\right)^2\right] \leq K [R(\theta) - R(\overline{B})].$$

As assumptions $\text{Margin}(K)$ and $\text{PhiMix}(\mathcal{C})$ won’t be used before Section 5, we postpone examples to this section.

4. Slow rates oracle inequalities

In this section, we give oracle inequalities in the sense of Equation 2 with slow rates of convergence $\Delta_j(n, \epsilon)$. The proofs of these results are given in Section 10. Note that the results concerning the Gibbs estimator are actually corollaries of a general result, Theorem 7, stated in Section 9. We introduce the following notation for the sake of shortness.

Definition 8.

When $\text{Bound}(B)$, $\text{LipLoss}(K)$, $\text{Lip}(L_j)$ and $\text{WeakDep}(\mathcal{C})$ are satisfied, we say that the model $\Theta$ satisfies Assumption $\text{SlowRates}(K_j)$ for $K_j := K(1 + L_j)(B + C)/\sqrt{2}$. 

71
4.1. The experts selection problem with slow rates

Consider the so-called $V$-aggregation problem \cite{51} with a finite set of predictors.

**Theorem 1.**

Assume that $|\Theta| = N \in \mathbb{N}$ and that $\text{SlowRates}(\kappa)$ is satisfied for $\kappa > 0$. Let $\pi$ be the uniform probability distribution on $\Theta$. Then the oracle inequality (2) is satisfied by the Gibbs estimator $\hat{\theta}_\lambda$ for $\lambda > 0$, $\varepsilon > 0$ with

$$
\Delta(n, \varepsilon) = \frac{2\lambda\kappa^2}{n(1-k/n)^2} + \frac{2\log(2N/\varepsilon)}{\lambda}.
$$

The choice of $\lambda$ in practice in this example is not trivial. The choice $\lambda = \sqrt{\log(N)/n}$ yields the oracle inequality:

$$
R(\hat{\theta}_\lambda) \leq R(\theta) + 2\sqrt{\frac{\log(N)}{n}} \left( \frac{\kappa}{1-k/n} \right)^2 + \frac{2\log(2/\varepsilon)}{\sqrt{n\log(N)}}
$$

This choice is not optimal and one would like to choose $\lambda$ as the minimizer of the upper bound

$$
\frac{2\lambda\kappa^2}{n(1-k/n)^2} + \frac{2\log(N)}{\lambda}.
$$

But $\kappa = \kappa(K, L, B, C)$ and the constants $B$ and $C$ are, usually, unknown. However, under our assumptions, the ERM predictor reaches the same bound without any calibration parameter.

**Theorem 2.**

Assume that $|\Theta| = M$ and that $\text{SlowRates}(\kappa)$ is satisfied for $\kappa > 0$. Then the ERM estimator $\hat{\theta}_{\text{ERM}}$ satisfies the oracle inequality (2) for any $\varepsilon > 0$ with

$$
\Delta(n, \varepsilon) = \inf_{\lambda > 0} \left[ \frac{2\lambda\kappa^2}{n(1-k/n)^2} + \frac{2\log(2N/\varepsilon)}{\lambda} \right] = \frac{4\kappa}{1-k/n} \sqrt{\frac{\log(2N/\varepsilon)}{n}}.
$$

We now discuss the optimality of these results. First, note that to our knowledge, no lower bounds for estimation under dependence assumption are known in this context. But, as iid observations satisfy our weak dependence assumptions, we can compare our upper bounds to the lower bounds known in the iid case. In the context of a finite parameter set and bounded outputs, the optimal rate in the iid case still depends on the loss function. For the absolute loss, it is proved in \cite{6}, Theorem 8.3 p. 1618 that the rate $\sqrt{\log(N)/n}$ cannot be improved. This means that the rates in Theorems 1 and 2 cannot be improved without any additional assumption.

4.2. The Gibbs and ERM estimators when $M = 1$

In the previous subsection we focused on the case where $\Theta$ is a finite set. Here we deal with the general case, in the sense that $\Theta$ can be either finite or infinite. Note that we won’t consider model selection issues in this subsection, say $M = 1$. The case where $\Theta = \cup_{i=1}^M \Theta_i$ with $M > 1$ is postponed to the next subsection.

**Theorem 3.**

Assume that $\text{SlowRates}(\kappa)$ and $\text{Dim}(d, D)$ are satisfied. Then the oracle inequality (2) is satisfied for the Gibbs estimator $\hat{\theta}_\lambda$ for $\lambda > 0$ with

$$
\Delta(n, \varepsilon) = \frac{2\lambda\kappa^2}{n(1-k/n)^2} + \frac{d\log(De\lambda/d) + \log(2/\varepsilon)}{\lambda}.
$$
Here again $\lambda = O(\sqrt{n/d})$ yields slow rates of convergence $O(\sqrt{d/n}\log n)$. But an exact minimization of the bound with respect to $\lambda$ is not possible as the constant $\kappa$ is not known and cannot be estimated efficiently (estimations of the weak dependence coefficients are too conservative in practice). A similar oracle inequality holds for the ERM estimator, that does not require any calibration, but this time, this result requires a more restrictive assumption on the structure of $\Theta$ (see Remark 1 below).

**Theorem 4.**  
Assume that $\Theta = \{\theta \in \mathbb{R}^d : \|\theta\| \leq R\}$ for some $R > 0$, and that SlowRates($\kappa$) holds on the extended model $\Theta' = \{\theta \in \mathbb{R}^d : \|\theta\| \leq R + 1\}$. If L1($\psi$) is satisfied then the oracle inequality (2) is satisfied for any $\varepsilon > 0$ with

$$\Delta(n, \varepsilon) = 2 \inf_{k \geq 2K\psi/d} \left[ \frac{\lambda k^2}{n(1 - k/n)} + \frac{d \log (2eK\psi(R + 1)\lambda/d) + \log (2/\varepsilon)}{\lambda} \right].$$

For $n$ sufficiently large and $\lambda = ((1 - k/n)/\kappa)\sqrt{d/n} \geq 2K\psi/d$ we obtain the oracle inequality

$$R(\hat{\theta}^{\text{ERM}}) \leq R(\tilde{\theta}) + \frac{2\kappa}{1 - k/n} \left( \sqrt{\frac{d}{n}} \log \left( \frac{2eK\psi(R + 1)}{\kappa} \frac{1}{\sqrt{d}} \sqrt{\frac{n}{\lambda}} \right) + \frac{\log (2/\varepsilon)}{\sqrt{d/n}} \right).$$

Thus, the ERM procedure achieves predictions that are close to the oracle, with a slow rate of convergence. On the one hand, this rate of convergence can be improved under more restrictive assumption on the loss, the parameter spaces and the observations. On the other hand, the general result holds for any quantile losses and any parameter spaces in bijection with a $\ell^1$ ball in $\mathbb{R}^d$. In particular it applies very easily to linear predictors of any orders.

**Example 6.**  
When $\Theta = \{\theta \in \mathbb{R}^d : \|\theta\| \leq R\}$, the linear AR predictors with $j$ parameters satisfy Lip($L$) with $L = R + 1$. The assumptions of Theorem 4 are satisfied with $d = j$ and $\psi = B$. Moreover, thanks to Remark 1 below, the assumptions of Theorem 3 are satisfied with $D = (KB \vee K^2B^2)(R + 1)$.

Note that the context of Theorem 4 are less general than the one of Theorem 3:

**Remark 1.**  
Under the assumptions of Theorem 4 we have for any $\theta \in \Theta$

$$R(\theta) - R(\tilde{\theta}) = \mathbb{E} \left[ g \left( \hat{X}^\theta - X_1 \right) - g \left( \hat{X}^{\tilde{\theta}} - X_1 \right) \right] \leq \mathbb{E} \left[ K \left\| \hat{X}^\theta - \hat{X}^{\tilde{\theta}} \right\| \right] \leq K\psi \|\theta - \tilde{\theta}\|_1.$$

Consider the Gibbs estimator with prior distribution $\pi$ uniform on $\Theta' = \{\theta \in \mathbb{R}^d : \|\theta\|_1 \leq R + 1\}$. We have

$$\log \frac{1}{\pi \{\theta : R(\theta) - R(\tilde{\theta}) < \delta\}} \leq \log \frac{1}{\pi \{\theta : \|\theta - \tilde{\theta}\|_1 < \frac{\delta}{K\psi}\}} \leq d \log \left( \frac{K\psi(R + 1)}{\delta} \right)$$

when $\delta/K\psi \leq 1$.

$$\leq d \log (K\psi(R + 1))$$

otherwise.

Thus, in any case,

$$\log \frac{1}{\pi \{\theta : R(\theta) - R(\tilde{\theta}) < \delta\}} \leq d \log \left( \frac{(K\psi \vee K^2\psi^2)(R + 1)}{\delta} \right)$$

and $\text{Dim}(d, D)$ is satisfied for $d = d$ and $D = (K\psi \vee K^2\psi^2)(R + 1)$.
Remark 2.
We obtain oracle inequalities for the ERM on parameter spaces in bijection with the \(L_1\)-ball in \(\mathbb{R}^d\). The rates of convergence are \(O(\sqrt{d/n} \log n)\). In the iid case, procedures can achieve the rates \(O(\sqrt{\log(d)/n})\) which is optimal as shown by [39] - but, to our knowledge, lower bounds in the dependent case are still an open issue. It nevertheless indicates that the ERM procedure might not be optimal in the setting considered here. Note however that, as the results on the Gibbs procedure are more general, they do not require the parameter space to be an \(L_1\)-ball. For example, when \(\Theta\) is finite, one can deduce a result similar to Theorem 1 from Theorem 3. This proves that Theorem 3 cannot be improved in general.

4.3. Model aggregation through the Gibbs estimator

We know tackle the case \(\Theta = \cup_{j=1}^M \Theta_j\) with \(M \geq 1\). In this case, it is convenient to define the prior \(\pi\) as \(\pi = \sum_{1 \leq i \leq M} p_i \pi_i\) where \(\pi_i(\Theta_i) = 1, p_i \geq 0\) and \(\sum_{1 \leq i \leq M} p_i = 1\).

Theorem 5.
Assume that SlowRates(\(\kappa_j\)) and Dim\((d_j, D_j)\) are satisfied for all \(1 \leq j \leq M\). For each \(\theta \in \Theta\), as there is only one \(j\) such that \(\theta \in \Theta_j\), we define \(\kappa(\theta) := \kappa_j\). Define a modified Gibbs estimator as:

\[
\hat{\theta}_j = \int \theta \hat{p}_j(d\theta) \text{ where } \hat{p}_j(d\theta) \propto \exp\left(-\lambda r_j(\theta) - \frac{\lambda^2 \kappa(\theta)^2}{n(1 - \frac{\lambda}{\kappa})}\right) \pi(d\theta)
\]

(note that when all the \(L_j\) are equal, this coincides with the Gibbs estimator \(\hat{\theta}_j\)). Let us define the grid \(\Lambda = \{2^0, 2^1, 2^2, \ldots\} \cap [1, n]\) and

\[
\hat{\lambda} = \arg \min_{\lambda \in \Lambda} \left\{ \int r_j(\theta) + \frac{\lambda \kappa(\theta)^2}{n(1 - k/n)^2} \hat{p}_j(d\theta) + \frac{K(\hat{p}_j, \pi)}{\hat{\lambda}} \right\}.
\]

Then, with probability at least \(1 - \epsilon\),

\[
R(\hat{\theta}_j) \leq \min_{1 \leq j \leq M} \left\{ R(\tilde{\theta}_j) + \inf_{\lambda \in [1, \hat{\lambda}]} \left[ \frac{4\lambda \kappa_j^2}{n(1 - k/n)^2} + 2 \frac{d_j \log \frac{2\sqrt{n \lambda}}{d_j}}{\epsilon p_j} + \log \left( \frac{2\log(2\alpha)}{\epsilon p_j} \right) \right] \right\}.
\]

Note that when \(M \leq n\), the choice \(p_j = 1/M\) leads to a rate \(O(\sqrt{d_j/n} \log(n))\). However, when the number of model is large, this is not a good choice. Calibration of \(p_j\) is discussed in details in [7], the choice \(p_j = \exp(-d_j)\), when possible, has the advantage that it does not deteriorate the rate of convergence.

Note that it is possible to prove a similar result for a penalized ERM (or SRM) under additional assumptions: \(L_1(\Psi_j)\) for each model \(\Theta_j\). However, as for the Gibbs estimator, the SRM requires the knowledge of \(\kappa_j\), so there is no advantage at all in using the SRM instead of the Gibbs estimator in the model selection setup.

5. Fast rates oracle inequalities

5.1. Discussion on the assumptions

In this section, we provide oracle inequalities like (2) with fast rates of convergence \(\Delta_j(n, \epsilon) = O(d_j/n)\). One need additional restrictive assumptions.

- now \(p = 1\), i.e. the process \((X_t)_{t \in \mathbb{Z}}\) is real-valued;
- we assume additionally Margin(\(\mathcal{K}\)) for some \(\mathcal{K} > 0\);
- the dependence condition WeakDep(\(\mathcal{C}\)) is replaced by PhiMix(\(\mathcal{C}\)).
As stated above, the margin (or Bernstein) assumption is required even in the iid setting to achieve fast rates. We provide now some examples of processes satisfying the uniform mixing assumption: PhiMix(\mathcal{C}). In the three following examples \((\epsilon_i)\) denotes an iid sequence (called the innovations).

**Example 7 (AR\((p)\) process).**
Consider the stationary solution \((X_t)\) of an AR\((p)\) model: \(\forall t \in \mathbb{Z}, X_t = \sum_{j=1}^{p} a_j X_{t-j} + \epsilon_t\). Assume that \((\epsilon_t)\) is bounded with a distribution possessing an absolutely continuous component. If \(A(z) = \sum_{j=1}^{p} a_j z^j\) has no root inside the unit disk in \(\mathbb{C}\), then \((X_t)\) is a geometrically \(\phi\)-mixing process, see [5], and PhiMix(\mathcal{C}) is satisfied for some \(\mathcal{C}\).

**Example 8 (MA\((p)\) process).**
Consider the stationary process \((X_t)\) such that \(X_t = \sum_{j=1}^{p} b_j \epsilon_{t-j}\) for all \(t \in \mathbb{Z}\). By definition, the process \((X_t)\) is stationary and \(\phi\)-dependent - it is even \(p\)-dependent, in the sense that \(\phi_r = 0\) for \(r > p\). Thus PhiMix(\mathcal{C}) is satisfied for some \(\mathcal{C} > 0\).

**Example 9 (Non linear processes).**
For extensions of the AR\((p)\) model of the form \(X_t = F(X_{t-1}, \ldots, X_{t-p}; \epsilon_t)\), the stationary solution is \(\phi\)-mixing, the coefficients are estimated and can satisfy PhiMix(\mathcal{C}). See e.g. [50].

We now provide an example of a predictive model satisfying all the assumptions required to obtain fast rates oracle inequalities, in particular Margin(\kappa), when the loss function \(\ell\) is quadratic, i.e. \(\ell(x, x') = (x - x')^2\):

**Example 10.**
Consider Example 2 where

\[ l_\theta(X_{t-1}, \ldots, X_{t-k}) = \sum_{i=1}^{N} \theta_i \varphi_i(X_{t-1}, \ldots, X_{t-k}), \]

for functions \((\varphi_i)_{i=0}^{\infty}\) of \((\mathbb{R}^p)^k\) to \(\mathbb{R}^p\), and \(\theta = (\theta_1, \ldots, \theta_\varphi) \in \mathbb{R}^N\). Assume the \(\varphi_i\) upper bounded by \(1\) and \(\Theta = \{\theta \in \mathbb{R}^N, ||\theta||_1 \leq L\}\) such that Lip(\(L\)) is satisfied. Moreover LipLoss(\(K\)) is satisfied with \(K = 4\mathcal{B}\). Assume that \(\overline{\theta} = \arg\min_{\theta \in \mathbb{R}^N} R(\theta) \in \Theta\) in order to have:

\[ \mathbb{E} \left\{ \left( \sum_{i=1}^{N} \left( \varphi_i(X_{t-1}, \ldots, X_{t-k}) - l_\theta(X_{t-1}, \ldots, X_{t-k}) \right)^2 \right)^{1/2} \right\} \]
\[ \leq \mathbb{E} \left\{ \left( l_\theta(X_{t-1}, \ldots, X_{t-k}) - \overline{l}(X_{t-1}, \ldots, X_{t-k}) \right)^2 + \left( \overline{l}(X_{t-1}, \ldots, X_{t-k}) - l_\theta(X_{t-1}, \ldots, X_{t-k}) \right)^2 \right\} \]
\[ \leq 16 \mathcal{B}^2 (1 + L)^2 \left[ R(\overline{\theta}) - R(\overline{\theta}) \right] \text{ by Pythagorean theorem.} \]

Assumption Margin(\(\mathcal{K}\)) is satisfied with \(\mathcal{K} = 16 \mathcal{B}^2 (1 + L)^2\). According to Theorem 6 below, the oracle inequality with fast rates holds as soon as Assumption PhiMix(\(\mathcal{C}\)) is satisfied.

We introduce the following notation for the sake of shortness.

**Definition 9.**
When Margin(\(\mathcal{K}\)), LipLoss(\(\mathcal{K}\)), Bound(\(\mathcal{B}\)), PhiMix(\(\mathcal{C}\)), Lip(\(\mathcal{L}\)) are satisfied, we will say for short that \(\Theta\) satisfies Assumption FastRates(\(\kappa\)) for \(\kappa := 4\mathcal{K}\mathcal{C}(4 \lor L\mathcal{B})\).
5.2. Gibbs estimator for model selection

We only give oracle inequalities for the Gibbs estimator in the model-selection setting. Obviously, when there is only one model, all the results can be obtained by taking $M = 1$ (in this case, this result can be extended to the ERM predictor at the cost of additional assumptions, so we won’t present any results on the ERM here).

**Theorem 6.**
Assume that FastRates($\kappa$) and Dim($d_j, D_j$) hold for any $j \in \{1, \ldots, M\}$. Then for $\lambda = (n - k)/\kappa$, we obtain the oracle inequality (1) is satisfied with

$$\Delta(n, \epsilon) = 4 \inf_j \left\{ R(\theta_j) - R(\bar{\theta}) + \frac{d_j \log \left( \frac{D_j (n - k)}{16 \kappa \epsilon^2} \right) + \log \left( \frac{2}{\epsilon_0} \right)}{n - k} \right\}.$$  

Compare with the slow rates case, we don’t have to optimize with respect to $\lambda$ as the optimal order for $\lambda$ is independent of $j$. In practice, the value of $\lambda$ provided by Theorem 6 is too conservative. In the iid case, it is shown in [29] that the value $\lambda = n/(4\sigma^2)$, where $\sigma^2$ is the variance of the noise of the regression yields good results. In our simulations, we will use $\lambda = n/\text{var}(X)$, where $\text{var}(X)$ is the empirical variance of the observed time series.

The rate $d/n$ is known to be optimal in the i.i.d. case for the quadratic loss, see e.g. (1.3) page 1676 in [14]. Let us compare the rates in Theorem 6 to the ones in [1, 22, 47, 49]. In [47, 49], the rate $1/n$ is never obtained. The paper [1] proves fast rates for online algorithms that are also computationally efficient, see also [22]. The fast rate $1/n$ is achieved when the coefficients ($\phi_j$) are geometrically decreasing. In other cases, the rate is slower. Note that we do not suffer such a restriction: we only need the partial sums of the coefficients to converge. The Gibbs estimator of Theorem 6 can also be computed efficiently thanks to MCMC procedures, see [3, 29].

5.3. Corollary: sparse autoregression

Consider the linear predictors

$$\hat{X}_t^0 = \theta_0 + \sum_{i=1}^j X_{t-i} \theta_i.$$  

For any $J \subset \{1, \ldots, p\}$, define the model:

$$\Theta_J = \{ \theta \in \mathbb{R}^p : ||\theta||_1 \leq L \text{ and } \theta_j \neq 0, j \in J \}.$$  

Let us remark that we have the disjoint union $\Theta = \bigcup_{J \subset \{1, \ldots, p\}} \Theta_J = \{ \theta \in \mathbb{R}^p : ||\theta||_1 \leq L \}$. We choose $\pi_j$ as the uniform probability measure on $\Theta_j$ and $\rho_j = 2^{-||J||-1} (\rho_{|J|})^{-1}$.

**Corollary 1.**
Assume that PhiMix($C$) is satisfied for some $C > 0$ as well as Bound($B$). Then the oracle inequality (1) is satisfied with

$$\Delta(n, \epsilon) = \text{cst} \frac{\bar{J} \log \left( (n - k) \rho_{|\bar{J}|} \right)}{n - k} + \log \left( \frac{2}{\epsilon_0} \right)$$  

for some constant $\text{cst} = \text{cst}(B, C, L)$ and where $\bar{J}$ is the unique subset of $\{1, \ldots, p\}$ such that $\bar{\theta} \in \Theta_{\bar{J}}$.

This extends the results of [3, 29, 35] to the case of autoregression. The upper bound is optimal up to the $n$ in the log term, see e.g. (1.3) page 1676 in [14].

**Proof.** The proof follows the computations of Example 10 that we do not reproduce here: we check the conditions LipLoss($K$) with $K = 4B$, Lip($L$) and Margin($K$) with $K = 16B^2 (1 + L)^2$. We can apply Theorem 6 with $d_j = |J|$ and $D_j = L$. □
6. Application to French GDP forecasting

6.1. Uncertainty in GDP forecasting

Every quarter \( t \geq 1 \), the French national bureau of statistics, INSEE (Institut National de la Statistique et des Etudes Economiques http://www.insee.fr/), publishes the growth rate of the French GDP (Gross Domestic Product). Since it involves a huge amount of data that take months to be collected and processed, the computation of the GDP growth rate \( \log(GDP_t/GDP_{t-1}) \) takes a long time (two years). This means that at time \( t \), the value \( \log(GDP_t/GDP_{t-1}) \) is actually not known. However, a preliminary value of the growth rate is published 45 days only after the end of the current quarter \( t \). This value is called a flash estimate and is the quantity that INSEE forecasters actually try to predict, at least in a first time. As we want to work under the same constraint as the INSEE, we will now focus on the prediction on the flash estimate and let \( \Delta GDP_t \) denote this quantity. To forecast at time \( t \), we will use:

1. the past forecastings \( \Delta GDP_j, 0 < j < t \) (it has been checked that to replace past flash estimates by the actual GDP growth rate when it becomes available do not improve the quality of the forecasting\cite{46});
2. past climate indicators \( I_j, 0 < j < t \), based on business surveys.

Business surveys are questionnaires of about ten questions sent monthly to a representative panel of French companies (see \cite{24} for more details). As a consequence, these surveys provide informations from the economic decision makers. Moreover, they are available each end of months and thus can be used to forecast the french GDP. INSEE publishes a composite indicator, the French business climate indicator that summarizes informations of the whole business survey, see \cite{19,25}. Following \cite{20}, let \( I_t \) be the mean of the last three (monthly based) climate indicators available for each quarter \( t > 0 \) at the date of publication of \( \Delta GDP_t \). All these values (GDP, climate indicator) are available from the INSEE website. Note that a similar approach is used in other countries, see e.g. \cite{8} on forecasting the European Union GDP growth thanks to EUROSTATS data.

In order to provide a quantification of the uncertainty of the forecasting, associated interval confidences are usually provided. The ASA and the NBER started using density forecasts in 1968, while the Central Bank of England and INSEE provide their prediction with a fan chart provided. Moreover, they are available each end of months and thus can be used to forecast the french GDP. INSEE publishes a composite indicator, the French business climate indicator that summarizes informations of the whole business survey, see \cite{19,25}. Following \cite{20}, let \( I_t \) be the mean of the last three (monthly based) climate indicators available for each quarter \( t > 0 \) at the date of publication of \( \Delta GDP_t \). All these values (GDP, climate indicator) are available from the INSEE website. Note that a similar approach is used in other countries, see e.g. \cite{8} on forecasting the European Union GDP growth thanks to EUROSTATS data.

In order to provide a quantification of the uncertainty of the forecasting, associated interval confidences are usually provided. The ASA and the NBER started using density forecasts in 1968, while the Central Bank of England and INSEE provide their prediction with a fan chart, see \cite{30,62} for surveys on density forecasting and \cite{11} for fan charts.

However, the statistical methodology used is often crude and, until 2012, the fan charts provided by the INSEE was based on the homoscedasticity of the Gaussian forecasting errors, see \cite{20,27}. However, empirical evidences are

1. the GDP forecasting is more uncertain in a period of crisis or recession;
2. the forecasting errors are not symmetrically distributed.

6.2. Application of Theorem 4 for the GDP forecasting

Define \( X_t \) as the data observed at time \( t \): \( X_t = (\Delta GDP_t, I_t) \in \mathbb{R}^2 \). We use the quantile loss function (see Example 5 page 71) for some \( 0 < \tau < 1 \) of the quantity of interested \( \Delta GDP_t \):

\[
\ell_{\tau}(\Delta GDP_t, I_t, \Delta GDP_t') = \begin{cases} \tau (\Delta GDP_t - \Delta GDP_t'), & \text{if } \Delta GDP_t - \Delta GDP_t' > 0 \\ (1 - \tau) (\Delta GDP_t - \Delta GDP_t'), & \text{otherwise}. \end{cases}
\]

We use the family of forecasters proposed by \cite{20} given by the relation

\[
f_{\theta}(X_{t-1}, X_{t-2}) = \theta_0 + \theta_1 \Delta GDP_{t-1} + \theta_2 I_{t-1} + \theta_3 (I_{t-1} - I_{t-2}) I_{t-1} - I_{t-2}
\]

where \( \theta = (\theta_0, \theta_1, \theta_2, \theta_3) \in \Theta(\mathcal{B}) \). Fix \( D > 0 \) and

\[
\Theta = \left\{ \theta = (\theta_0, \theta_1, \theta_2, \theta_3) \in \mathbb{R}^4, ||\theta||_1 = \sum_{i=0}^{3} |\theta_i| \leq D \right\}.
\]
Let us denote \( R^*(\theta) \) := \( E[\ell_r(\Delta GDP_t, f_\theta(X_{t-1}, X_{t-2}))] \) the risk of the forecaster \( f_\theta \) and let \( r^*_\theta \) denote the associated empirical risk. We let \( \hat{\delta}^{\text{ERM}, \tau} \) denote the ERM with quantile loss \( \ell_r \):

\[
\hat{\delta}^{\text{ERM}, \tau} \in \arg\min_{\delta \in \Theta} r^*_\theta(\theta).
\]

We apply Theorem 4 as \( \text{Lip}(L) \) is satisfied \( \Theta' \) with \( L = D + 1 \) and \( \text{LipLoss}(K) \) with \( K = 1 \). If the observations are bounded, stationary such that \( \text{WeakDep}(C) \) holds for some \( C > 0 \), the assumptions of Theorem 4 are satisfied with \( \psi = B \) and \( d = 4 \):

**Corollary 2.**

Let \( \tau \in (0, 1) \). If the observations are bounded, stationary such that \( \text{WeakDep}(C) \) holds for some \( C > 0 \) then for any \( \varepsilon > 0 \) and \( n \) large enough, we have

\[
P \left( R^*(\hat{\delta}^{\text{ERM}, \tau}) \leq \inf_{\delta \in \Theta} R^*(\theta) + \frac{2\kappa\sqrt{2}}{\sqrt{n}(1 - 4/n)} \log \left( \frac{2e^2B(D + 1)^{\sqrt{n}}}{\kappa\varepsilon} \right) \right) \geq 1 - \varepsilon.
\]

In practice the choice of \( D \) has little importance as soon as \( D \) is large enough (only the theoretical bound is influenced). As a consequence we take \( D = 100 \) in our experiments.

### 6.3. Results

The results are shown in Figure 1 for forecasting corresponding to \( \tau = 0.5 \). Figure 2 represents the confidence intervals of order 50\%, i.e. \( \tau = 0.25 \) and \( \tau = 0.75 \) (left) and for confidence interval of order 90\%, i.e. \( \tau = 0.05 \) and \( \tau = 0.95 \) (right). We report only the results for the period 2000-Q1 to 2011-Q3 (using the period 1988-Q1 to 1999-Q4 for learning).

![Fig 1](image-url)

**Fig 1.** French GDP forecasting using the quantile loss function with \( \tau = 0.5 \).

We denote \( \hat{\delta}^{\text{ERM}, \tau}[t] \) the estimator computed at time \( t - 1 \), based on the observations \( X_j, j < t \). We report the online performance:

\[
\text{mean abs. pred. error} = \frac{1}{n} \sum_{t=1}^{n} |\Delta GDP_t - \hat{f}_{\text{ERM}, \tau}(X_{t-1}, X_{t-2})| \\
\text{mean quad. pred. error} = \frac{1}{n} \sum_{t=1}^{n} (\Delta GDP_t - \hat{f}_{\text{ERM}, \tau}(X_{t-1}, X_{t-2}))^2
\]

and compare it to the INSEE performance, see Table 1. We also report the frequency that the GDPs fall above the predicted \( \tau \)-quantiles for each \( t \), see Table 2. Note that this quantity should be close to \( \tau \).

The methodology fails to forecast the importance of the 2008 subprime crisis as it was the case for the INSEE forecaster, see [20]. However, it is interesting to note that the confidence interval is larger at that date: the forecast is less reliable, but thanks to our adaptive confidence interval, it would have been possible to know at that time that the prediction was not reliable. Another interesting point is that the lower bound of the confidence intervals are varying over time while the upper bound is almost constant for \( \tau = 0.95 \). It supports the idea of asymmetric forecasting errors. A parametric model with gaussian innovations would lead to underestimate the recessions risk.
Fig 2. French GDP online 50%-confidence intervals (left) and 90%-confidence intervals (right).

7. Simulation study

In this section, we finally compare the ERM or Gibbs estimators to the Quasi Maximum Likelihood Estimator (QMLE) based method used by the R function ARMA [52]. We want to check that the ERM and Gibbs estimators can be safely used in various contexts as their performances are close to the standard QMLE even in the context where the series is generated from an ARMA model. It is also the opportunity to check the robustness of our estimators in case of misspecification.

7.1. Parametric family of predictors

Here, we compare the ERM to the QMLE. We draw simulations from an AR(1) models (4) and a non linear model (5):

$$X_t = 0.5X_{t-1} + \epsilon_t$$  \hspace{1cm} (4)

$$X_t = 0.5 \sin(X_{t-1}) + \epsilon_t$$  \hspace{1cm} (5)

where $\epsilon_t$ are iid innovations. We consider two cases of distributions for $\epsilon_t$: the uniform case, $\epsilon_t \sim U[-a, a]$, and the Gaussian case, $\epsilon_t \sim N(0, \sigma^2)$. Note that, in the first case, both models satisfy the assumptions of Theorem 6: there
exists a stationary solution \((X_t)\) that is \(\phi\)-mixing when the innovations are uniformly distributed and \textbf{WeakDep}(C) is satisfied for some \(C > 0\). This paper does not provide any theoretical results for the Gaussian case as it is unbounded. However, we refer the reader to [7] for truncations techniques that allows to deal with this case too. We fix \(\sigma = 0.4\) and \(a = 0.70\) such that \(\text{Var}(\epsilon_t) \simeq 0.16\) in both cases. For each model, we simulate first a sequence of length \(n\) and then we predict \(X_n\) using the observations \((X_1, \ldots, X_{n-1})\). Each simulation is repeated 100 times and we report the mean quadratic prediction errors on the Table 3.

It is interesting to note that the ERM estimator with absolute loss performs better on model (4) while the ERM with quadratic loss performs slightly better on model (5). The difference tends be too small to be significative, however, the numerical results tends to indicate that both methods are robust to model mispecification. Also, both estimators seem to perform better than the R QMLE procedure when \(n = 100\), but the differences tends to be less perceptible when \(n\) grows.

### 7.2. Sparse autoregression

To illustrate Corollary 1, we compare the Gibbs predictor to the model selection approach of the ARMA procedure in the R software. This procedure computes the QMLE estimator in each AR\((p)\) model, \(1 \leq p \leq q\), and then selects the order \(p\) by Akaike’s AIC criterion [2]. The Gibbs estimator is computed using a Reversible Jump MCMC algorithm described in Section 4 in the preprint version of [3] (available on arXiv as \texttt{http://arxiv.org/pdf/1009.2707v1.pdf}). The parameter \(\lambda\) is taken as \(\lambda = n/\text{var}(X)\), the empirical variance of the observed time series.

We draw the data according to the following models:

\[
X_t = 0.5X_{t-1} + 0.1X_{t-2} + \epsilon_t, \quad \text{AR}[2] \quad (6)
\]

\[
X_t = 0.6X_{t-4} + 0.1X_{t-8} + \epsilon_t, \quad \text{AR}[8] \quad (7)
\]

\[
X_t = \cos(X_{t-1}) \sin(X_{t-2}) + \epsilon_t, \quad \text{AR}[2] \quad (8)
\]

where \(\epsilon_t\) are iid innovations. We still consider the uniform \((\epsilon_t \sim U[-a, a])\) and the Gaussian \((\epsilon_t \sim N(0, \sigma^2))\) cases with \(a = 0.4\) and \(a = 0.70\). We compare the Gibbs predictor performances to those of the estimator based on the AIC criterion and to the QMLE in the AR\((q)\) model, so called "full model". For each model, we first simulate a time series of length \(2n\), use the observations 1 to \(n\) as a learning set and \(n + 1\) to \(2n\) as a test set, for \(n = 100\) and \(n = 1000\). Each simulation is repeated 20 times and we report in Table 4 the mean and the standard deviation of the empirical quadratic errors for each method and each model.

The three procedures seem not significatively different. Although notice that the Gibbs predictor performs better on Models (7) and (8) while the AIC predictor performs slightly better on Model (6). Note that the Gibbs predictor performs also well in the case of a Gaussian noise where the boundedness assumption is not satisfied.

Table 3. Performances of the ERM estimators and ARMA, on the simulations. The first row “ERM abs.” is for the ERM estimator with absolute loss, the second row “ERM quad.” for the ERM with quadratic loss. The standard deviations are given in parentheses.

8. Conclusion

This paper provides oracle inequalities for the empirical risk minimizer and the Gibbs estimator that generalizes earlier results by Catoni [17] to the context of time series forecasting. While essentially theoretical, these results are used in a real-life example with promising results. Future work might include a more intensive simulation study. Probably, more efficient Monte-Carlo algorithms should be investigated. Just before we submitted the final version of this paper, a preprint appeared on arXiv [58] where the computation time needed to compute an accurate approximation of the estimator by Monte-Carlo is upper-bounded. This is a very promising research direction. Equally important, on the theoretical side, while the assumptions needed to obtain the slow rates of convergence are rather general, the assumptions we used to get the fast rates are restrictive. Further work will include an investigation on the optimality of these assumptions.

Acknowledgements

We would like to thank the anonymous referees for their constructive remarks. We also would like to thank Pr. Olivier Catoni, Pascal Massart and Alexandre Tsybakov for insightful comments on preliminary versions of this work.

References

9. A general PAC-Bayesian inequality

Theorems 1 and 3 are actually both corollaries of a more general result that we would like to state for the sake of completeness. This result is the analogous of the PAC-Bayesian bounds proved by Catoni in the case of iid data [17].

**Theorem 7 (PAC-Bayesian Oracle Inequality for the Gibbs estimator).**

Let us assume that \( \text{LowRates}(\kappa) \) is satisfied for some \( \kappa > 0 \). Then, for any \( \lambda, \varepsilon > 0 \) we have

\[
P \left\{ R(\hat{\theta}_\lambda) \leq \inf_{\rho \in \mathcal{M}_1(\Theta)} \left[ \int R d\rho + \frac{2\lambda \kappa^2}{n (1 - k/n)^2} + \frac{2K(\rho, \pi) + 2 \log (2/\varepsilon)}{\lambda} \right] \right\} \geq 1 - \varepsilon.
\]

This result is proved in Appendix 10, but we can now provide the proofs of Theorems 1 and 3.

**Proof of Theorem 1.** We apply Theorem 7 for \( \pi = \frac{1}{M} \sum_{\theta \in \Theta} \delta_{\theta} \) and restrict the inf in the upper bound to Dirac masses \( \rho \in \{ \delta_{\theta} / \theta \in \Theta \} \). We obtain

\[
R(\hat{\theta}_\lambda) \leq \inf_{\delta > 0} \left[ \int R d\rho + \frac{2\lambda \kappa^2}{n (1 - k/n)^2} + \frac{2 \log (2M/\varepsilon)}{\lambda} \right].
\]

**Proof of Theorem 3.** An application of Theorem 7 yields that with probability at least \( 1 - \varepsilon \)

\[
R(\hat{\theta}_\lambda) \leq \inf_{\rho \in \mathcal{M}_1(\Theta)} \left[ \int R d\rho + \frac{2\lambda \kappa^2}{n (1 - k/n)^2} + \frac{2 \log (2/\varepsilon)}{\lambda} \right].
\]

Let us estimate the upper bound at the probability distribution \( \rho_\delta \) defined as

\[
d\rho_\delta = \frac{1 \{ R(\theta) - R(\overline{\theta}) < \delta \}}{\int_{\theta \in \Theta} 1 \{ R(\theta) - R(\overline{\theta}) < \delta \} \pi(\theta)}.
\]

Then we have:

\[
R(\hat{\theta}_\lambda) \leq \inf_{\delta > 0} \left[ R(\overline{\theta}) + \frac{2\lambda \kappa^2}{n (1 - k/n)^2} + \frac{2 \log (2M/\varepsilon)}{\lambda} \right].
\]

Under the assumptions of Theorem 3 we have:

\[
R(\hat{\theta}_\lambda) \leq \inf_{\delta > 0} \left[ R(\overline{\theta}) + \frac{2\lambda \kappa^2}{n (1 - k/n)^2} + \frac{d \log (D/\delta) + \log (\hat{\delta})}{\lambda} \right].
\]

The infimum is reached for \( \delta = d/\lambda \) and we have:

\[
R(\hat{\theta}_\lambda) \leq R(\overline{\theta}) + \frac{2\lambda \kappa^2}{n (1 - k/n)^2} + \frac{d \log (D/\lambda d) + \log (\hat{\delta})}{\lambda}.
\]
10. Proofs

10.1. Preliminaries

We will use Rio’s inequality [53] that is an extension of Hoeffding’s inequality in a dependent context. For the sake of completeness, we provide here this result when the observations \( \{X_1, \ldots, X_N\} \) come from a stationary process \( \{X_t\} \).

**Lemma 1 (Rio [53]).**

Let \( h \) be a function \( (\mathbb{R}^d)^n \to \mathbb{R} \) such that for all \( x_1, \ldots, x_n, y_1, \ldots, y_n \in \mathbb{R}^d \),

\[
|h(x_1, \ldots, x_n) - h(y_1, \ldots, y_n)| \leq \sum_{i=1}^n ||x_i - y_i||. \tag{9}
\]

Then, for any \( t > 0 \), we have

\[
\mathbb{E}(\exp(t \{ \mathbb{E}[h(X_1, \ldots, X_N)] - h(X_1, \ldots, X_N) \})) \leq \exp \left( \frac{t^2 n \{ B + \theta_{\infty,n}(1) \}^2}{2} \right).
\]

Others exponential inequalities can be used to obtain PAC-Bounds in the context of time series: the inequalities in [26, 54] for mixing time series, and [23, 65] under weakest “weak dependence” assumptions, [57] for martingales. Lemma 1 is very general and yields optimal low rates of convergence. For fast rates of convergence, we will use Samson’s inequality that is an extension of Bernstein’s inequality in a dependent context.

**Lemma 2 (Samson [54]).**

Let \( N \geq 1, (Z_i)_{i \in \mathbb{Z}} \) be a stationary process on \( \mathbb{R}^d \) and \( \phi^2 \) denote its \( \phi \)-mixing coefficients. For any measurable function \( f : \mathbb{R}^d \to [-M, M] \) any \( 0 \leq t \leq 1/(MK^2_{\phi^2}) \), we have

\[
\mathbb{E}(\exp(t(S_N(f) - \mathbb{E}S_N(f)))) \leq \exp \left( 8K_{\phi^2} N \sigma^2(f)t^2 \right),
\]

where \( S_N(f) := \sum_{i=1}^N f(Z_i) \), \( K_{\phi^2} = 1 + \sum_{t=1}^N \sqrt{\phi^2} \) and \( \sigma^2(f) = \text{Var}(f(Z_i)) \).

Proof of Lemma 2. This result can be deduced easily from the proof of Theorem 3 of [54] which states a more general result on empirical processes. In page 457 of [54], replace the definition of \( f_N(x_1, \ldots, x_n) \) by \( f_N(x_1, \ldots, x_n) = \sum_{i=1}^n g(x_i) \) (following the notations of [54]). Then check that all the arguments of the proof remain valid, the claim of Lemma 2 is obtained page 460, line 7.

We also remind the variational formula of the Kullback divergence.

**Lemma 3 (Donsker-Varadhan [31] variational formula).**

For any \( \pi \in \mathcal{M}_1^+(E) \), for any measurable upper-bounded function \( h : E \to \mathbb{R} \) we have:

\[
\int \exp(h) d\pi = \exp \left( \sup_{\rho \in \mathcal{M}_1^+(E)} \left( \int h d\rho - K(\rho, \pi) \right) \right). \tag{10}
\]

Moreover, the supremum with respect to \( \rho \) in the right-hand side is reached for the Gibbs measure \( \pi\{ h \} \) defined by \( \pi\{ h \}(dx) = e^{hx} \pi(dx)/\pi(\exp(h)) \).

Actually, it seems that in the case of discrete probabilities, this result was already known by Kullback (Problem 8.28 of Chapter 2 in [43]). For a complete proof of this variational formula, even in the non integrable cases, we refer the reader to [15, 17, 31].
10.2. Technical lemmas for the proofs of Theorems 2, 4, 5 and 7

**Lemma 4.**
We assume that $\text{LowRates}(\kappa)$ is satisfied for some $\kappa > 0$. For any $\lambda > 0$ and $\theta \in \Theta$ we have

$$
\mathbb{E}\left(e^{\lambda(R(\theta) - c_{\kappa}(\theta))}\right) \vee \mathbb{E}\left(e^{\lambda(c_{\kappa}(\theta) - R(\theta))}\right) \leq \exp\left(\frac{\lambda^2 \kappa^2}{n(1 - kn)^2}\right).
$$

**Proof of Lemma 4.** Let us fix $\lambda > 0$ and $\theta \in \Theta$. Let us define the function $h$ by:

$$
h(x_1, \ldots, x_n) = \frac{1}{K(1 + L)} \sum_{i=1}^{n} \ell(f_{\theta}(x_{-i}, \ldots, x_{-k}), x_i).
$$

We now check that $h$ satisfies (9), remember that $\ell(x, x') = g(x - x')$ so

$$
\left|h(x_1, \ldots, x_n) - h(y_1, \ldots, y_n)\right| \leq \frac{1}{1 + L} \sum_{i=1}^{n} \left|\ell(f_{\theta}(x_{-i}, \ldots, x_{-k}) - f_{\theta}(y_{-i}, \ldots, y_{-k}) - y_i)\right|
$$

where we used Assumption LipLoss($K$) for the last inequality. So we have

$$
\left|h(x_1, \ldots, x_n) - h(y_1, \ldots, y_n)\right| \leq \frac{1}{1 + L} \sum_{i=1}^{n} \left(\sum_{j=1}^{k} a_j(\theta)\|x_{-j} - y_{-j}\| + \|x_i - y_i\|\right)
$$

where we used Assumption Lip($L$). So we can apply Lemma 1 with $h(X_1, \ldots, X_n) = \frac{n-k}{K(1+L)} c_{\kappa}(\theta)$, $\mathbb{E}(h(X_1, \ldots, X_n)) = \frac{n-k}{K(1+L)} R(\theta)$, and $t = K(1 + L) \lambda/(n - k)$:

$$
\mathbb{E}\left(e^{\lambda(R(\theta) - c_{\kappa}(\theta))}\right) \leq \exp\left(\frac{\lambda^2 K^2(1 + L)^2 (B + \theta_{\max}(1))^2}{2n(1 - kn)^2}\right) \leq \exp\left(\frac{\lambda^2 K^2(1 + L)^2 (B + C)^2}{2n(1 - \frac{L}{n})^2}\right)
$$

by Assumption WeakDep($C$). This ends the proof of the first inequality. The reverse inequality is obtained by replacing the function $h$ by $-h$. 

We are now ready to state the following key Lemma.

**Lemma 5.**
Let us assume that $\text{LowRates}(\kappa)$ is satisfied satisfied for some $\kappa > 0$. Then for any $\lambda > 0$ we have

$$
P\left\{ \begin{array}{l}
\forall \rho \in \mathcal{M}_+(\Theta), \\
\int R d\rho \leq \int r_\rho d\rho + \frac{\alpha^2}{\alpha(1 - k/n)^2} + \frac{K(\rho, \gamma) + \log(2/c)}{\lambda} \\
\text{and} \\
\int r_\rho d\rho \leq \int R d\rho + \frac{\alpha^2}{\alpha(1 - k/n)^2} + \frac{K(\rho, \gamma) + \log(2/c)}{\lambda}
\end{array} \right\} \geq 1 - \varepsilon.
$$
Proof of Lemma 5. Let us fix $\theta > 0$ and $\lambda > 0$, and apply the first inequality of Lemma 4. We have:

$$\mathbb{E}\left( \exp \left( \lambda \left( R(\theta) - r_n(\theta) - \frac{\lambda \kappa^2}{n(1-k/n)^2} \right) \right) \right) \leq 1,$$

and we multiply this result by $\epsilon/2$ and integrate it with respect to $\pi(d\theta)$. An application of Fubini’s Theorem yields

$$\mathbb{E} \int \exp \left( \lambda (R(\theta) - r_n(\theta)) - \frac{\lambda \kappa^2}{n(1-k/n)^2} - \log (2/\epsilon) \right) \pi(d\theta) \leq \frac{\epsilon}{2}.$$

We apply Lemma 3 and we get:

$$\mathbb{E} \exp \left( \sup_{\rho} \left\{ \lambda \int (R(\theta) - r_n(\theta)) \rho(d\theta) - \frac{\lambda \kappa^2}{n(1-k/n)^2} - \log (2/\epsilon) - \mathcal{K}(\rho, \pi) \right\} \right) \leq \frac{\epsilon}{2}.$$

As $e^x \geq 1_{R_x}(x)$, we have:

$$\mathbb{P} \left\{ \sup_{\rho} \int \left( R(\theta) - r_n(\theta) \right) \rho(d\theta) - \frac{\lambda \kappa^2}{n(1-k/n)^2} - \log (2/\epsilon) - \mathcal{K}(\rho, \pi) \geq 0 \right\} \leq \frac{\epsilon}{2}.$$

Using the same arguments than above but starting with the second inequality of Lemma 4:

$$\mathbb{E} \exp \left( \lambda \left( r_n(\theta) - R(\theta) - \frac{\lambda \kappa^2}{n(1-k/n)^2} \right) \right) \leq 1.$$

we obtain:

$$\mathbb{P} \left\{ \sup_{\rho} \int \left( r_n(\theta) - R(\theta) \right) \rho(d\theta) - \frac{\lambda \kappa^2}{n(1-k/n)^2} - \log \left( \frac{2}{\epsilon} \right) - \mathcal{K}(\rho, \pi) \geq 0 \right\} \leq \frac{\epsilon}{2}.$$

A union bound ends the proof.

The following variant of Lemma 5 will also be useful.

Lemma 6. Let us assume that LowRates($\kappa$) is satisfied for some $\kappa > 0$. Then for any $\lambda > 0$ we have

$$\mathbb{P} \left\{ \forall \rho \in \mathcal{M}_+^1(\Theta), \int R d\rho \leq \int r_n d\rho + \frac{\lambda \kappa^2}{n(1-k/n)^2} + \frac{\mathcal{K}(\rho, \pi) + \log(2/\epsilon)}{\lambda} \right\} \geq 1 - \epsilon.$$

Proof of Lemma 6. Following the proof of Lemma 5 we have:

$$\mathbb{P} \left\{ \sup_{\rho} \left\{ \lambda \int (R(\theta) - r_n(\theta)) \rho(d\theta) - \frac{\lambda \kappa^2}{n(1-k/n)^2} - \log (2/\epsilon) - \mathcal{K}(\rho, \pi) \right\} \geq 0 \right\} \leq \frac{\epsilon}{2}.$$

Now, we use the second inequality of Lemma 4, with $\theta = \overline{\Theta}$:

$$\mathbb{E} \left( \exp \left( \lambda \left( r_n(\overline{\Theta}) - R(\overline{\Theta}) - \frac{\lambda \kappa^2}{n(1-k/n)^2} \right) \right) \right) \leq 1.$$

But then, we directly apply Markov’s inequality to get:

$$\mathbb{P} \left\{ r_n(\overline{\Theta}) \geq R(\overline{\Theta}) + \frac{\lambda \kappa^2}{n(1-k/n)^2} + \frac{\log (2/\epsilon)}{\lambda} \right\} \leq \frac{\epsilon}{2}.$$

Here again, a union bound ends the proof.
10.3. Proof of Theorems 7 and 5

In this subsection we prove the general result on the Gibbs predictor.

Proof of Theorem 7. We apply Lemma 5. So, with probability at least \(1 - \varepsilon\) we are on the event given by (11). From now, we work on that event. The first inequality of (11), when applied to \(\hat{p}_r(d\theta)\), gives

\[
\int R(\theta)\hat{p}_r(d\theta) \leq \int r_n(\theta)\hat{p}_r(d\theta) + \frac{\lambda \kappa^2}{n(1 - k/n)^2} + \frac{1}{\lambda} \log \left(\frac{2}{\varepsilon}\right) + \frac{1}{\lambda} K(\hat{p}_r, \pi).
\]

According to Lemma 3 we have:

\[
\int r_n(\theta)\hat{p}_r(d\theta) + \frac{1}{\lambda} K(\hat{p}_r, \pi) = \inf_{\rho} \left( \int r_n(\theta)\rho(d\theta) + \frac{1}{\lambda} K(\rho, \pi) \right)
\]

so we obtain

\[
\int R(\theta)\hat{p}_r(d\theta) \leq \inf_{\rho} \left\{ \int r_n(\theta)\rho(d\theta) + \frac{\lambda \kappa^2}{n(1 - k/n)^2} + \frac{K(\rho, \pi) + \log \left(\frac{2}{\varepsilon}\right)}{\lambda} \right\}.
\] (12)

We now estimate from above \(r(\theta)\) by \(R(\theta)\). Applying the second inequality of (11) and plugging it into Inequality 12 gives

\[
\int R(\theta)\hat{p}_r(d\theta) \leq \inf_{\rho} \left\{ \int R \rho + \frac{2}{\lambda} K(\rho, \pi) + \frac{2\lambda \kappa^2}{n(1 - k/n)^2} + \frac{2}{\lambda} \log \left(\frac{2}{\varepsilon}\right) \right\}.
\]

We end the proof by the remark that \(\theta \mapsto R(\theta)\) is convex and so by Jensen’s inequality \(\int R(\theta)\hat{p}_r(d\theta) \geq R \left( \int \theta \hat{p}_r(d\theta) \right) = R(\hat{\theta}_r)\).

Proof of Theorem 5. Follow, for each \(\lambda \in \Lambda\), the proof of Lemma 5 with \(\kappa(\theta)\) instead of \(\kappa\), and fixed confidence level \(\varepsilon/|\Lambda| > 0\). We obtain, for all \(\lambda \in \Lambda\),

\[
P \left\{ \forall \rho \in \mathcal{M}_1^\lambda(\Theta), \right.
\]

\[
\int R \rho \leq \int \left[ r_n(\theta) + \frac{\lambda \kappa(\theta)^2}{n(1 - k/n)^2} \right] \rho(d\theta) + \frac{K(\rho, \pi) + \log \left(\frac{2\lambda}{\varepsilon}\right)}{\lambda} \geq 1 - \varepsilon/|\Lambda|.
\]

A union bound provides:

\[
P \left\{ \forall \lambda \in \Lambda, \forall \rho \in \mathcal{M}_1^\lambda(\Theta), \right.
\]

\[
\int R \rho \leq \int \left[ r_n(\theta) + \frac{\lambda \kappa(\theta)^2}{n(1 - k/n)^2} \right] \rho(d\theta) + \frac{K(\rho, \pi) + \log \left(\frac{2\lambda}{\varepsilon}\right)}{\lambda} \geq 1 - \varepsilon.
\] (13)

From now, we only work on that event of probability at least \(1 - \varepsilon\). Remark that

\[
R(\hat{\theta}) = R(\hat{\theta}_r) \leq \int R(\theta)\hat{p}_r(d\theta) \text{ by Jensen’s inequality}
\]

\[
\leq \int \left[ r_n(\theta) + \frac{\lambda \kappa(\theta)^2}{n(1 - k/n)^2} \right] \hat{p}_r(d\theta) + \frac{K(\hat{p}_r, \pi) + \log \left(\frac{2\lambda}{\varepsilon}\right)}{\lambda}
\]

by (13)

\[
= \min_{d \in \Lambda} \left\{ \int \left[ r_n(\theta) + \frac{\lambda \kappa(\theta)^2}{n(1 - k/n)^2} \right] \hat{p}_r(d\theta) + \frac{K(\hat{p}_r, \pi) + \log \left(\frac{2\lambda}{\varepsilon}\right)}{\lambda} \right\}
\]

88
We restrict the inf as, for any \( \lambda \) on \( 1 \) have, with probability at least \( \delta \) by Lemma 3.

\[
\min_{\theta \in \Theta} \left\{ \int \left[ r_n(\theta) + \frac{\lambda \kappa(\theta)^2}{n (1 - k/n)^2} \right] \rho(d\theta) + \frac{\mathcal{K}(\rho, \pi) + \log \left( \frac{2N^2}{\delta} \right)}{\lambda} \right\}
\]

\[
\min_{\theta \in \Theta} \left\{ \int \left[ R(\theta) + \frac{2 \lambda \kappa(\theta)^2}{n (1 - k/n)^2} \right] \rho(d\theta) + 2 \frac{\mathcal{K}(\rho, \pi) + \log \left( \frac{2N^2}{\delta} \right)}{\lambda} \right\}
\]

Let us now prove the results about the ERM.

10.4. Proof of Theorems 2 and 4

We apply Lemma 6. So we have, with probability at least \( 1 - \varepsilon \),

\[
\begin{align*}
\forall \rho \in \mathcal{M}_1^+(\Theta), \quad \int R d\rho &\leq \int r_n d\rho + \frac{\lambda \kappa^2}{n (1 - k/n)^2} + \frac{\mathcal{K}(\rho, \pi) + \log(2|\lambda|)}{\lambda} \\
\text{and} \quad r_n(\theta) &\leq R(\theta) + \frac{\lambda \kappa^2}{n (1 - k/n)^2} + \frac{\mathcal{K}(\rho, \pi) + \log(2|\lambda|)}{\lambda}.
\end{align*}
\]

We restrict the inf in the first inequality to Dirac masses \( \rho \in \{ \delta_\theta, \theta \in \Theta \} \) and we obtain:

\[
\begin{align*}
\forall \theta \in \Theta, \quad R(\theta) &\leq r_n(\theta) + \frac{\lambda \kappa^2}{n (1 - k/n)^2} + \frac{\log(2|\lambda|)}{\lambda} \\
\text{and} \quad r_n(\theta) &\leq R(\theta) + \frac{\lambda \kappa^2}{n (1 - k/n)^2} + \frac{\log(2|\lambda|)}{\lambda}.
\end{align*}
\]

In particular, we apply the first inequality to \( \hat{\theta}^{\text{ERM}} \). We remind that \( \overline{\theta} \) minimizes \( R \) on \( \Theta \) and that \( \hat{\theta}^{\text{ERM}} \) minimizes \( r_n \) on \( \Theta \), and so we have

\[
\begin{align*}
R(\hat{\theta}^{\text{ERM}}) &\leq r_n(\hat{\theta}^{\text{ERM}}) + \frac{\lambda \kappa^2}{n (1 - k/n)^2} + \frac{\mathcal{K}(\rho, \pi) + \log(2|\lambda|)}{\lambda} \\
&\leq r_n(\overline{\theta}) + \frac{\lambda \kappa^2}{n (1 - k/n)^2} + \frac{\mathcal{K}(\rho, \pi) + \log(2|\lambda|)}{\lambda} \\
&\leq R(\overline{\theta}) + \frac{2 \lambda \kappa^2}{n (1 - k/n)^2} + \frac{\mathcal{K}(\rho, \pi) + \log(2|\lambda|)}{\lambda} \\
&\leq R(\overline{\theta}) + \frac{2 \lambda \kappa^2}{n (1 - k/n)^2} + \frac{2 \log(2|\lambda|)}{\lambda}.
\end{align*}
\]

as, for any \( \lambda \in [1, n] \), there is \( \lambda' \in \Lambda \) such that \( \lambda' \leq \lambda \leq 2\lambda' \). Finally, note that \(|\lambda| \leq \log_2(n) + 1 = \log_2(2n)\).

\[\square\]
The result still holds if we choose \( \lambda \) as a minimizer of
\[
\frac{2\lambda k^2}{n(1-k/n)^2} + \frac{2\log (2M/\varepsilon)}{\lambda}.
\]

**Proof of Theorem 4.** Let us denote \( \Theta' = \{ \theta \in \mathbb{R}^d : \|\theta\|_1 \leq D + 1 \} \) and \( \pi \) as the uniform probability distribution on \( \Theta' \).

We apply Lemma 6. So we have, with probability at least \( 1 - \varepsilon \),
\[
\forall \rho \in \mathcal{M}_1(\Theta'), \int R d\rho \leq \int r_\rho d\rho + \frac{\lambda k^2}{n(1-k/n)^2} + \frac{K(\rho, \pi) + \log (2/\varepsilon)}{\lambda}.
\]

So for any \( \rho \),
\[
R(\hat{\theta}^{\text{ERM}}) = \int [R(\hat{\theta}^{\text{ERM}}) - R(\theta)] \rho(d\theta) + \int R d\rho
\]
\[
\leq \int [R(\hat{\theta}^{\text{ERM}}) - R(\theta)] \rho(d\theta) + \int r_\rho d\rho + \frac{\lambda k^2}{n(1-k/n)^2} + \frac{K(\rho, \pi) + \log (2/\varepsilon)}{\lambda}
\]
\[
\leq \int [R(\hat{\theta}^{\text{ERM}}) - R(\theta)] \rho(d\theta) + \int [r_\rho - r_\rho(\hat{\theta}^{\text{ERM}})] \rho(d\theta) + \frac{\lambda k^2}{n(1-k/n)^2} + \frac{K(\rho, \pi) + \log (2/\varepsilon)}{\lambda}
\]
\[
\leq 2K\psi \int \left\| \theta - \hat{\theta}^{\text{ERM}} \right\|_1 \rho(d\theta) + r_\rho(\bar{\theta}) + \frac{\lambda k^2}{n(1-k/n)^2} + \frac{K(\rho, \pi) + \log (2/\varepsilon)}{\lambda}
\]
\[
\leq 2K\psi \int \left\| \theta - \hat{\theta}^{\text{ERM}} \right\|_1 \rho(d\theta) + R(\bar{\theta}) + \frac{2\lambda k^2}{n(1-k/n)^2} + \frac{K(\rho, \pi) + \log (2/\varepsilon)}{\lambda}.
\]

Now we define, for any \( \delta > 0 \), \( \rho_\delta \) by
\[
\frac{d\rho_\delta}{d\pi}(\theta) = \frac{1\{ \left\| \theta - \hat{\theta}^{\text{ERM}} \right\| < \delta \}}{\int_{t \in \Theta'} 1\{ \left\| t - \hat{\theta}^{\text{ERM}} \right\| < \delta \} \pi(dt)}.
\]

So in particular, we have, for any \( \delta > 0 \),
\[
R(\hat{\theta}^{\text{ERM}}) \leq 2K\psi \delta + R(\bar{\theta}) + \frac{2\lambda k^2}{n(1-k/n)^2} + \frac{\log \left( \int_{t \in \Theta'} 1\{ \left\| t - \hat{\theta}^{\text{ERM}} \right\| < \delta \} \pi(dt) \right)}{\lambda} + \frac{2\log (2/\varepsilon)}{\lambda}.
\]

But for any \( \delta \leq 1 \),
\[
-\log \int_{t \in \Theta'} 1\{ \left\| t - \hat{\theta}^{\text{ERM}} \right\| < \delta \} \pi(dt) = d \log \left( \frac{D + 1}{\delta} \right).
\]

So we have
\[
R(\hat{\theta}^{\text{ERM}}) \leq \inf_{\delta \leq 1} \left\{ 2K\psi \delta + R(\bar{\theta}) + \frac{2\lambda k^2}{n(1-k/n)^2} + \frac{d \log \left( \frac{2D+1}{\delta} \right)}{\lambda} + \frac{2\log (2/\varepsilon)}{\lambda} \right\}.
\]

We optimize this result by taking \( \delta = d/(2K\psi) \), which is smaller than 1 as soon as \( \lambda \geq 2K\psi/d \), we get:
\[
R(\hat{\theta}^{\text{ERM}}) \leq R(\bar{\theta}) + \frac{2\lambda k^2}{n(1-k/n)^2} + \frac{d \log \left( \frac{2D+1}{d} \right)}{\lambda} + \frac{2\log (2/\varepsilon)}{\lambda}.
\]

We just choose \( \lambda \) as the minimizer of the r.h.s., subject to \( \lambda \geq 2K\psi/d \), to end the proof. □
10.5. Some preliminary lemmas for the proof of Theorem 6

**Lemma 7.** Under the hypothesis of Theorem 6, we have, for any $\theta \in \Theta$, for any $0 \leq \lambda \leq (n-k)/(2kKLBC)$,

$$
\mathbb{E} \exp \left\{ \lambda \left[ 1 - \frac{8kC\lambda}{n-k} \right] \left( R(\theta) - R(\overline{\theta}) - r(\theta) + r(\overline{\theta}) \right) \right\} \leq 1,
$$

and

$$
\mathbb{E} \exp \left\{ \lambda \left[ 1 + \frac{8kC\lambda}{n-k} \right] \left( R(\theta) - R(\overline{\theta}) - r(\theta) + r(\overline{\theta}) \right) \right\} \leq 1.
$$

**Lemma 7.** We apply Lemma 2 to $N = n - k$, $Z_i = (X_{i+1}, \ldots, X_{i+k})$.

$$
\ell(Z) = \frac{1}{n-k} \left[ R(\theta) - R(\overline{\theta}) - \ell(X_{i+k}, f_\theta(X_{i+k-1}, \ldots, X_{i+1})) + \ell(X_{i+k}, f_{\overline{\theta}}(X_{i+k-1}, \ldots, X_{i+1}))^2 \right],
$$

and so

$$
S_n(\ell) = [R(\theta) - R(\overline{\theta}) - r(\theta) + r(\overline{\theta})],
$$

and the $Z_i$ are uniformly mixing with coefficients $\phi_i^2 = \phi[1/l]$. Note that $1 + \sum_{i=1}^{n-q} \sqrt{\phi_i^2} = 1 + \sum_{i=1}^{n-q} \sqrt{\phi[1/k]} \leq kC$ by PhiMix(C). For any $\theta$ and $\theta'$ in $\Theta$ let us put

$$
V(\theta, \theta') = \mathbb{E} \left\{ \left[ \ell(X_{i+k+1}, f_\theta(X_k, \ldots, X_1)) - \ell(X_{i+k+1}, f_{\theta'}(X_k, \ldots, X_1)) \right] \right\}.
$$

We are going to apply Lemma 2. Remark that $\sigma^2(\ell) \leq V(\theta, \overline{\theta})/(n-k)^2$. Also,

$$
\left| \ell(X_{i+k}, f_\theta(X_{i+k-1}, \ldots, X_{i+1})) - \ell(X_{i+k}, f_{\overline{\theta}}(X_{i+k-1}, \ldots, X_{i+1})) \right| \leq K |f_\theta(X_{i+k-1}, \ldots, X_{i+1}) - f_{\overline{\theta}}(X_{i+k-1}, \ldots, X_{i+1})| \leq KLB
$$

where we used LipLoss(K) for the first inequality and Lip(\ell) and PhiMix(B, C) for the second inequality. This implies that $||f||_\infty \leq 2KLB/(n-k)$, so we can apply Lemma 2 for any $0 \leq \lambda \leq (n-k)/(2kKLBC)$, we have

$$
\ln \mathbb{E} \exp \left\{ \lambda \left( R(\theta) - R(\overline{\theta}) - r(\theta) + r(\overline{\theta}) \right) \right\} \leq \frac{8kCV(\theta, \overline{\theta})\lambda^2}{n-k}.
$$

Notice finally that Margin(\mathcal{K}) leads to

$$
V(\theta, \overline{\theta}) = K \left[ R(\theta) - R(\overline{\theta}) \right]
$$

This proves the first inequality of Lemma 7. The second inequality is proved exactly in the same way, but replacing $f$ by $-f$.

We are now ready to state the following key Lemma.

**Lemma 8.** Under the hypothesis of Theorem 6, we have, for any $0 \leq \lambda \leq (n-k)/(2kKLBC)$, for any $0 < \varepsilon < 1$,

$$
P \left\{ \begin{array}{ll}
\forall \phi \in \mathcal{M}_{\lambda}(\Theta), \\
(1 - \frac{8kC\lambda}{n-k}) \left( \int R d\phi - R(\overline{\theta}) \right) \leq \int r d\phi - r(\overline{\theta}) + \frac{K[\phi, \overline{\theta} + \log(2/\varepsilon)]}{\lambda} \\
\text{and} \\
\int r d\phi - r(\overline{\theta}) \leq \left( \int R d\phi - R(\overline{\theta}) \right) \left( 1 + \frac{8kC\lambda}{n-k} \right) + \frac{K[\phi, \overline{\theta} + \log(2/\varepsilon)]}{\lambda} \end{array} \right\} \geq 1 - \varepsilon.
$$
Proof of Lemma 8. Let us fix $\epsilon$, $\lambda$ and $\theta \in \Theta$, and apply the first inequality of Lemma 7. We have:

$$
\mathbb{E} \exp \left\{ \lambda \left( 1 - \frac{8kC}{n-k} \right) \left( R(\theta) - R(\overline{\theta}) \right) \right\} \leq 1,
$$

and we multiply this result by $\epsilon/2$ and integrate it with respect to $\pi(d\theta)$. Fubini’s Theorem gives:

$$
\mathbb{E} \int \exp \left\{ \lambda \left( 1 - \frac{8kC}{n-k} \right) \left( R(\theta) - R(\overline{\theta}) \right) \right\} \pi(d\theta) \leq \frac{\epsilon}{2}.
$$

We apply Lemma 3 and we get:

$$
\mathbb{E} \exp \left\{ \sup_{\rho} \lambda \left( 1 - \frac{8kC}{n-k} \right) \left( \int R d\rho - R(\overline{\theta}) \right) - \int r d\rho + r(\overline{\theta}) + \log(\epsilon/2) \right\} \leq \frac{\epsilon}{2}.
$$

As $e^x \geq 1 + x$, we have:

$$
P \left\{ \sup_{\rho} \lambda \left( 1 - \frac{8kC}{n-k} \right) \left( \int R d\rho - R(\overline{\theta}) \right) - \int r d\rho + r(\overline{\theta}) + \log(\epsilon/2) \right\} \leq \frac{\epsilon}{2}.
$$

Let us apply the same arguments starting with the second inequality of Lemma 7. We obtain:

$$
P \left\{ \sup_{\rho} \lambda \left( 1 + \frac{8kC}{n-k} \right) \left( R(\overline{\theta}) - \int R d\rho \right) - r(\overline{\theta}) + \int r d\rho + \log(\epsilon/2) - K(\rho, \pi) \right\} \geq 0 \leq \frac{\epsilon}{2}.
$$

A union bound ends the proof.

10.6. Proof of Theorem 6

Fix $0 \leq \lambda = (n-k)/(4kKLBC) \wedge (n-k)/(16kC) \leq (n-k)/(2kKLBC)$. Applying Lemma 8, we assume from now that the event of probability at least $1 - \epsilon$ given by this lemma is satisfied. In particular we have $\forall \rho \in M_1(\Theta)$,

$$
\int R d\rho - R(\overline{\theta}) \leq \frac{\int r d\rho - r(\overline{\theta}) + \frac{k(\rho, \pi) + \log(2/\epsilon)}{\delta}}{1 - \frac{4kC}{n-k}}.
$$

In particular, thanks to Lemma 3, we have:

$$
\int R d\hat{\rho}_\delta - R(\overline{\theta}) \leq \inf_{\rho \in M_1(\Theta)} \frac{\int r d\rho - r(\overline{\theta}) + \frac{k(\rho, \pi) + \log(2/\epsilon)}{\delta}}{1 - \frac{4kC}{n-k}}.
$$

Now, we apply the second inequality of Lemma 8:

$$
\int R d\hat{\rho}_\delta - R(\overline{\theta}) \leq \inf_{\rho \in M_1(\Theta)} \left( 1 + \frac{4kC}{n-k} \right) \left( \int R d\rho - R(\overline{\theta}) \right) + 2 \frac{k(\rho, \pi) + \log(2/\epsilon)}{\delta}
$$

$$
\leq \inf_{\rho \in M_1(\Theta)} \inf_{\delta > 0} \left( 1 + \frac{4kC}{n-k} \right) \left( R(\overline{\theta}) + \delta - R(\overline{\theta}) \right) + 2 \frac{d_1 \log \left( \frac{\delta}{\pi} \right) + \log(2/\epsilon)}{\delta}
$$

$$
\leq \inf_{\rho \in M_1(\Theta)} \inf_{\delta > 0} \left( 1 + \frac{4kC}{n-k} \right) \left( R(\overline{\theta}) + \delta - R(\overline{\theta}) \right) + 2 \frac{d_1 \log \left( \frac{\delta}{\pi} \right) + \log(2/\epsilon)}{\delta}.
$$
by restricting $\rho$ as in the proof of Theorem 3. First, notice that our choice $\lambda \leq (n - k)/(16kC)$ leads to

$$\int R d\hat{\rho} - R(\overline{\theta}) \leq 2 \inf_{j} \inf_{\delta > 0} \left\{ \frac{3}{2} \left[ R(\overline{\theta}) + \delta - R(\overline{\theta}) \right] + 2 \frac{d_j \log \left( \frac{D_j}{\delta} \right)}{\lambda} + \log \left( \frac{2}{\epsilon \lambda} \right) \right\}.$$

Taking $\delta = d_j/\lambda$ leads to

$$\int R d\hat{\rho} - R(\overline{\theta}) \leq 4 \inf_{j} \left\{ R(\overline{\theta}) - R(\overline{\theta}) + \frac{d_j \log \left( \frac{D_j}{\delta} \right)}{\lambda} + \log \left( \frac{2}{\epsilon \lambda} \right) \right\}.$$

Finally, we replace the last occurrences of $\lambda$ by its value:

$$\int R d\hat{\rho} - R(\overline{\theta}) \leq 4 \inf_{j} \left\{ R(\overline{\theta}) - R(\overline{\theta}) + \frac{d_j \log \left( \frac{D_j}{\delta} \right)}{\lambda(4k(4kC + 4kKLBC) n - k)} + \log \left( \frac{2}{\epsilon \lambda} \right) \right\}.$$

Jensen’s inequality leads to:

$$R \left( \hat{\theta}_j \right) - R(\overline{\theta}) \leq 4 \inf_{j} \left\{ R(\overline{\theta}) - R(\overline{\theta}) + 4k(4k(4kC + 4kKLBC) n - k) \frac{d_j \log \left( \frac{D_j}{\delta} \right)}{\lambda(4kC + 4kKLBC) n - k} + \log \left( \frac{2}{\epsilon \lambda} \right) \right\}.$$

\[\blacksquare\]
