Design for quality: reconfigurable flat optics based on active metasurfaces

<https://doi.org/10.1515/nanoph-2020-0033>

Received January 15, 2020; accepted July 10, 2020; published online July 29, 2020

Abstract: Optical metasurfaces, planar subwavelength nanoantenna arrays with the singular ability to sculpt wavefront in almost arbitrary manners, are poised to become a powerful tool enabling compact and high-performance optics with novel functionalities. A particularly intriguing research direction within this field is active metasurfaces, whose optical response can be dynamically tuned postfabrication, thus allowing a plurality of applications unattainable with traditional bulk optics. Designing reconfigurable optics based on active metasurfaces is, however, presented with a unique challenge, since the optical quality of the devices must be optimized at multiple optical states. In this article, we provide a critical review on the active meta-optics design principles and algorithms that are applied across structural hierarchies ranging from single meta-atoms to full meta-optical devices.

The discussed approaches are illustrated by specific examples of reconfigurable metasurfaces based on optical phase-change materials.

Keywords: deep neural network; inverse design; metasurface; meta-optics; phase-change material; reconfigurable.

1 Introduction

Reconfigurable optical systems allow dynamic optical response tuning and thus bring in dramatically expanded functionalities compared to their passive counterparts. The capability is conventionally realized by mechanical means, for example, in zoom lenses and deformable mirrors. However, the additional degrees of freedom (DOFs) usually impose significantly increased system complexity and size, as well as sensitivity to mechanical actuation accuracy. Optical metasurfaces consist of nanostructured meta-atoms arranged in subwavelength arrays that allow on-demand manipulation of the phase, amplitude, and polarization of light [1–8]. The promise of metasurface optics lies in the arbitrary control of electromagnetic waves with an optically thin form factor that cannot be obtained by traditional bulk optics. Passive metasurfaces have successfully demonstrated important spherical, chromatic, and angle-dependent aberration correction capabilities [9–18]. Integrated with active components, the flat, pixelated metasurface architecture further facilitates the local and global tuning of their optical responses. These tunable devices are customarily known as active metasurfaces.

Active metasurfaces have received concentrated attention recently, emerging as a promising area on the path toward practical implementations. While several review articles have covered the development of this field [19–26], we choose to approach this topic from a distinctive perspective by focusing on the design principles of active metasurfaces at optical frequencies (i.e., ultraviolet [UV] to infrared [IR]). We outline practical challenges and address how the design strategies are correlated to and can be

harnessed to improve the performance of such meta-optical devices. We quantitatively show that challenges for designing reconfigurable metasurfaces are exacerbated as compared to their passive counterparts since multiple objectives are typically required to realize a plurality of functionalities. Meanwhile, the active meta-optical device architecture demands a multiscale, multiphysics systematic design framework spanning from individual meta-atoms to macroscopic meta-optical systems.

In this paper, we first provide a critical review of the basic switching mechanisms to realize active metasurfaces and device implementations. This is followed by a comparison of key performance metrics, which are further specified based on various application requirements. As design complexity increases with performance goals, traditional meta-optic synthesis methods are confronted with accuracy, computation efficiency, and scaling challenges. To address such issues, we further discuss advanced design and optimization approaches suitable for multifunctional active metasurface optics. We then elaborate on the design principles and procedures for constructing active metasurfaces exemplified by the ones based on optical phase-change materials (O-PCMs). The same methods can be generically applied to other active metasurface platforms. In contrast to passive devices, the multiscale, multiphysics, and multi-objective nature of active metasurfaces requires a wholistic yet efficient design process bridging all critical phases across materials characterization, device fabrication, and system operation.

2 Active switching mechanisms: an overview

The tuning mechanisms in active metasurfaces at optical frequencies can, in general, be classified into two categories: lattice deformation, where spacing between meta-atoms is changed while their individual responses remain unmodified; and meta-atom tuning, where the optical properties of meta-atoms are modulated. In the latter approach, a number of mechanisms have been applied for direct modulation of meta-atom properties, including free carrier injection; thermo-optic [27], electro-optic, or magneto-optical [28–33] effects; O-PCMs; electrochemical processes; or optical nonlinearity.

2.1 Mechanical deformation or motion

Lattice deformation is most conveniently implemented by embedding meta-atoms inside an elastomer matrix. The

soft substrate can then withstand large strains, allowing continuous change of meta-atom spacing. Simultaneously, the meta-atoms experience negligible deformation or modification, as they are usually made of high-index semiconductors or dielectric materials with elastic moduli several orders of magnitude larger than the elastomer matrix. Many reconfigurable metasurface devices have been created based on this approach, including metalenses with variable focal lengths [34–36], switchable hologram [37], metasurfaces for dynamic coloration [38–40], and tunable resonant filters [41–43]. In addition to facilitating mechanical tuning of optical responses, such stretchable metasurfaces further foresee conformal integration on curvilinear surfaces of traditional refractive or reflective optical elements [9, 44, 45] or coupling with other flexible photonic components to achieve added functionalities [46–51]. Mechanical actuation of metasurface structures can also be driven by stimuli-responsive materials as an alternative to direct strain exertion [52, 53].

Besides lattice deformation, mechanical tuning of a meta-optical device can be implemented by relative motion of constituent metasurfaces with respect to each other or other optical elements. In this case, the individual metasurfaces can still be passive. For example, the focal length of a microelectromechanical system (MEMS)-tunable metalens can be varied by adjusting the spacing between two metasurfaces [54]. Other examples include tilting of MEMS-integrated metalens for beam steering [55] and relative displacement between metasurface plates for varifocal zoom imaging [56, 57].

2.2 Free carrier density modulation

Free carrier accumulation or depletion in conventional semiconductors and transparent conducting oxides (TCOs) induces complex refractive-index change via plasma dispersion effect [58–61]. Free carrier concentration in these materials can be controlled by leveraging all-optical techniques [62, 63]. However, it is more convenient to use the field effect in metal-oxide-semiconductor (MOS) capacitor structures [64–69] or semiconductor heterojunctions [70]. The free carrier-induced changes in the real and imaginary parts of the refractive index are useful for modulating the phase [65–68] and amplitude [69, 71, 72] of light. In addition to plasma dispersion effect, free carrier injection alters band filling in doped materials, leading to the Moss-Burstein effect [73] or Pauli blocking that shifts the optical absorption edge. The band filling effect is particularly pronounced in low-dimensional materials such as graphene as well as other 2-D compounds, which,

given their low carrier density, can be readily tuned via electrostatic gating [74–80]. This mechanism has been widely employed to demonstrate tunable plasmonic devices in the infrared spectral domain [81–86].

2.3 Thermo-optic tuning in semiconductors

Optical properties of semiconductors can also be controlled with temperature. At room temperature, the thermo-optic effect in conventional semiconductors is usually dominated by bound electron-phonon interactions [87] with small thermo-optic coefficients typically of the order of 10^{-4} K^{-1} . At elevated temperatures and/or high free carrier concentrations, thermal excitation of the carriers causes plasma frequency blue shift and, subsequently, leads to a drastic change in the thermo-optic coefficient [88]. For instance, an exceptionally large free carrier-induced index change (Δn up to 1.5) has been shown in InSb in the long-wave IR with a 435-K temperature swing [89]. Lead chalcogenides are another class of compounds with significant thermo-optic coefficients, although, unlike InSb, their thermo-optic response mainly originates from anomalous temperature-dependent bandgap dispersion rather than the free carrier effect [90]. As device implementation examples, switchable metasurface reflectors and beam deflectors have been realized capitalizing on thermo-optic effects in Si [91, 92].

2.4 Electro-refractive switching

While free carrier-based switching methods are versatile and amenable to on-chip integration, the simultaneous occurrence of refractive index and absorption changes imposes parasitic loss penalties, which compromises optical efficiency of devices and further introduces undesirable wavefront distortion. Pure index-only modulation can be accomplished through electro-refractive mechanisms. This mechanism of metasurface tuning often relies on electro-optic materials exemplified by electro-optic polymers [93, 94], liquid crystals [95–98], and multi-quantum wells [99]. In liquid crystals, the birefringent molecules can be reoriented along the electric field direction, thereby creating a large refractive-index change possibly exceeding 0.3 [100]. By immersing metasurface structures in a liquid crystal cell, electrical tuning of resonances in plasmonic [101–104] and dielectric [105, 106] resonator arrays has been demonstrated. Electrically tunable liquid crystal metasurfaces engineered using an inverse-design approach have demonstrated high-

efficiency and wide-angle steering performances [107]. Besides electrical tuning, it is also possible to thermally switch liquid crystals. By heating them up to above the phase-transition point, liquid crystals convert from the aligned nematic phase into an isotropic phase with disordered molecular orientations. Optical responses of metasurfaces in contact with liquid crystals can be modulated by harnessing the moderate change in refractive index [108–113] (typically of the order of 0.1) or change in chirality [114]. A major challenge of liquid crystal-based tuning is to separate modulation of phase and amplitude responses. This problem has been addressed by using transmissive phase-only nanoantennas immersed in a liquid crystal layer [113]. Magnetic field-assisted alignment [115] and photoisomerization [116, 117] are among the other viable switching mechanisms for liquid crystals. Overall, the relatively small refractive-index change innate to electro-optic media limits the phase coverage of tunable meta-atoms based on electro-refractive switching.

2.5 Optical phase-change media

Unlike electro-refractive effects which generate relatively small refractive index perturbations, optical phase-transition and phase-change materials boast gigantic refractive index contrast (with Δn usually well-exceeding unity) upon undergoing a solid-state phase transition. This unique behavior is identified in a handful of correlated oxides exemplified by vanadium dioxide (VO_2) [118–120] and chalcogenide compounds, such as Ge–Sb–Te (GST) or Ag–In–Sb–Te (AIST) alloys which switch between amorphous and crystalline phases [121–124]. The structural origins of the optical contrast in correlated oxides and chalcogenides are, however, fundamentally different. The oxides exhibit a Mott-type metal-insulator transition (MIT) where the optical property change is intimately linked to electron doping [125], whereas in the chalcogenide phase-change alloys, the refractive index contrast has been attributed to a nonvolatile change in the chemical bonding type [126–128]. The two classes of materials also rely upon distinctive switching methods. In VO_2 , the MIT is largely volatile. It is, however, possible to control the nucleation kinetics during MIT to engineer the hysteresis loop in VO_2 (e.g., via doping [129–131]), thereby introducing nonvolatile responses over a finite temperature window [132–136]. The MIT in VO_2 is most commonly induced by heating, although the transition can also be triggered via other stimuli such as electric field [137], terahertz pulses [138], or optical pumping [139, 140]. In contrast to VO_2 , the phase transformation of chalcogenide O-PCMs is predominantly

nonvolatile [141], and thus, the devices are “quasi-passive”, requiring power supply only during the active switching process. The transition between the amorphous and crystalline phases in chalcogenides can be actuated via laser pulses [142–146] or electrothermal heating with integrated microheaters [147–150].

The phase-transition and phase-change materials have enabled a wide variety of metasurface devices [151]. VO_2 has been applied to the frequency control of plasmonic antenna arrays [152–155], free-space phase [156, 157], amplitude [158–162] and polarization [163] modulators, plasmonic color generation [164, 165], adaptive thermal camouflage [166], tunable absorbers and emitters [167–171], and free-form metadevices [134]. Compared to VO_2 , chalcogenide O-PCMs exemplified by GST offer even larger optical contrast in the near-IR and UV spectral regimes with an index change up to 2.8 [172–176]. In addition to tuning response of identical meta-atom arrays [177–189], advanced active control of metasurface devices, including varifocal metalenses [190–193], metasurface color display [194], spatial light modulators [188], spectral filters [180, 187, 189], beam-steering metadvice [195], reconfigurable holograms [196], tunable thermal absorbers [197] and emitters [198–201], switches [202], free-form rewritable metasurfaces [203, 204], and topologically optimized metadevices [205], have also been experimentally demonstrated leveraging phase-change behavior of GST alloys.

While the vast majority of active metasurface applications have been based on the two archetypal composition groups of VO_2 and GST alloys, alternative O-PCMs affording enhanced performance attributes have also been actively explored. For instance, new correlated oxides with nonvolatile [206, 207] and tri-state phase transformation characteristics [208] have recently been discovered. Optical absorption losses, in particular, emanating from the metallic phase of correlated oxides and crystalline GST can severely compromise the optical efficiency and phase-tuning range of dielectric metasurface devices. Moreover, the small switching thickness of GST (bound by the heat dissipation rate during melt-quenching to < 100 nm [182]) limits field overlap with the active O-PCM medium and further constrains the attainable phase-tuning efficiency. A new O-PCM $\text{Ge}_2\text{Sb}_2\text{Se}_4\text{Te}_1$ (GSST) with broadband low optical loss in both phases and large switching volume has been developed to overcome these limitations [209–215]. As another example, the diminished optical contrast of GST in the visible spectrum has motivated the investigation of Sb_2S_3 as an alternative O-PCM suitable for active photonics in the visible regime [216, 217]. Phase-change materials based on other emerging systems such as halide perovskites and 2-D van der Waals crystals can potentially also be utilized for active metasurface tuning [218, 219].

2.6 Electrochemical modulation

Electrochemical methods have been employed to tune the optical responses of metasurface structures via two mechanisms. In the first scheme, the surface charge density of metals is modulated by an applied electrochemical potential, leading to changes in the metals’ plasmonic properties. Large wavelength shift of plasmonic antennas has been realized using this approach [220–222]. The second technique involves chemical changes of the meta-atoms instigated by electrochemical redox reactions in metals [223–226] or mobile ion intercalation in transition metal oxides [227]. Active metasurfaces with reversible and nonvolatile switching behavior have been materialized using this technique [227].

2.7 All-optical activation of metasurfaces

Using light to modulate active metasurfaces often relies upon nonlinear optical interactions such as Kerr nonlinearity, photogenerated free carrier injection, and photothermal effects [228]. It has been established that these nonlinear interactions can be significantly enhanced capitalizing on resonances in metasurfaces [229–235], and the optical behavior of the meta-atoms is in turn strongly modified by the nonlinear effects [236–239]. Besides optical nonlinearity, the properties of metasurfaces can also be actively controlled leveraging optical interference between the mutually coherent pump and probe light beams. By strategically placing a metasurface layer with subwavelength thickness at antinodes (or nodes) of the spatial interference pattern formed by the two beams, optical absorption by the metasurface can be enhanced (or suppressed) [240, 241]. Strictly speaking, this approach operates by varying external optical beams rather than directly reconfiguring the device properties. However, we note that such coherent absorption, when integrated with optically thin metasurface platforms, provides a facile route for active control of metadevices with diverse functions including switching, beam steering, and optical computing at extremely high bandwidths exceeding 100 THz [242–246].

2.8 Other mechanisms toward reconfigurable metasurfaces

Several other mechanisms have also been attempted for reconfiguring metasurfaces. Metasurface patterns can be rearranged by solvent-assisted dissolution reshaping [247], laser welding [248–252], laser-assisted growth [253] and

polymerization [254], or templated dewetting [255–258]. The optical properties of many metals are drastically altered upon hydrogenation [259], a useful trait that has been exploited in reconfigurable plasmonic metasurfaces [260–263]. These techniques present promising new solutions to reconfigure metasurface devices, although their throughput, cycling endurance (or reversibility), and scalability remain to be further investigated or optimized.

3 Active switching mechanisms: summary and performance benchmark

In Table 1, we summarize the main switching mechanisms used in active metasurfaces and compare the key performance metrics of these approaches.

In this table, the refractive index (real part) tuning range gives an approximate measure of the tuning capacity or switching contrast of metasurface devices, where large index change facilitates high-efficiency reconfigurable metasurface designs with low cross talk between different states. What is not listed is the modulation of the imaginary part of the refractive index accompanying the real part change. This coupling between index change and absorption is inherent to mechanisms where modulating free carrier density accounts for the optical contrast. The coupling is beneficial or even essential for many applications, such as on/off optical switching, dynamic thermal camouflage, adaptive perfect absorbers, and tunable plasmonics. For other applications, in particular, for transmissive meta-optical devices, optical loss penalties and wavefront distortion due to excess material absorption must be carefully mitigated.

Another consideration not explicitly accounted for in the table is the optical modal confinement. For example, in MOS structures, the index change is confined within the carrier depletion or accumulation regions of a few nanometers in thickness. In chalcogenide O-PCMs, the critical thickness is constrained by the need to rapidly cool down the material in re-amorphization cycles to prevent crystallization. The small active material thicknesses in these examples inevitably reduce mode field overlap and diminish the attainable tuning range.

For endurance or switching cycling lifetime, numbers representing the largest experimentally measured values in each class of devices are quoted. It should be noted that the numbers do not necessarily correspond to intrinsic lifetime limits of the technologies. For instance, stretchable electronic components based on elastomeric

materials have been demonstrated to sustain over one million deformation cycles [268], and there is ample reason to justify that stretchable optical devices can achieve similarly exceptional durability with judicious mechanical designs [269–271].

Similarly, the bandwidth numbers cited represent the state of the art and may not imply fundamental physical limits. Free carrier injection and multiquantum well-based devices can possibly be engineered to achieve modulation speeds well beyond 1 GHz [272–276]. In contrast, the bandwidth of active metasurfaces based on thermo-optic tuning and O-PCMs is often limited by the thermal time constant of the system to the MHz regime, despite the remarkably faster phase-transition kinetics of the materials [277, 278]. Meanwhile, it should be noted that the switching speed is also dependent on the device architecture, e.g., switching of individual unit cells or an array of unit cells.

Last but not least, individual meta-atom control unleashes the ultimate DOFs for active tuning of metasurface devices. To date, such fine control has only been experimentally implemented using optical means [134, 203] and to a limited extent (e.g., in 1-D metagratings [65, 71, 279]) using electrical actuation. Promising advances have also been made with individually addressed display pixels based on O-PCMs [280], and the scheme can potentially be scaled to higher spatial density for single meta-atom addressing. Alternatively, dimensionality reduction [281] offers a practical route to circumvent 2-D meta-atom manipulation with 1-D control for certain applications. Overall, electrical control of individual meta-atoms in dense 2-D arrays remains a critical research challenge yet to be overcome.

4 Applications of active metasurfaces

As summarized in Table 1, the performance of active metasurfaces can be gauged with several metrics including but not limited to switching contrast, cycling lifetime, speed, optical efficiency, power consumption, etc. It is important to emphasize that while some of the parameters are almost ubiquitously relevant (e.g., switching contrast and optical efficiency), others are useful only for specific applications (e.g., speed, cycling lifetime, and power consumption). In Table 2, we list the potential applications of active metasurfaces and assign relative importance of the different metrics. We must stress that the perceived importance of the performance parameters can also vary depending on the specific use cases even within an application domain, and thus, the table should be viewed as a general guideline and need not substitute case-by-case analysis.

Table 1: Switching mechanisms of active metasurfaces: the table compiles the best experimentally reported values to date, and the values listed do not necessarily represent fundamental limits to the performance metrics.

Type	Material or mechanism	Refractive index tuning range	Endurance (cycling lifetime)	Attainable bandwidth ^d	Individual meta-atom control	Volatility	Planar integration compatibility
Mechanical deformation	Elastic stretching	–	3000 [46] ^b	~1 Hz	–	–	N/A

5 Advanced design and optimization: toward multifunctional metasurfaces

By harnessing the electromagnetic multipoles within tunable meta-atoms, their optical responses can be controlled to precisely tailor the output wavefronts. However, such multipole responses can be very complicated and difficult to predict, sometimes even for simple geometries. This challenge escalates when the design domain expands from individual meta-atoms to metasurfaces and multifunctional metadevices. In addition, imperfections originating from material and device fabrication further complicate the design process. As a result, the design space rapidly becomes enormous, and the traditional brute-force searching approach for meta-atoms turns out to be extremely inefficient.

In this section, we discuss advanced design and optimization approaches that can be utilized to potentially address such multifunctional design tasks in an efficient and yet accurate manner. In dielectric metasurfaces, unit cells or meta-atoms are typically comprised of nano-antenna inclusions which are designed to produce a desired set of complex reflection and transmission coefficients [282]. In the optical and IR regimes, these nano-antennas are usually limited to simple canonical shapes such as triangles, rectangles, rings, cylinders, and their combinations. However, it has been shown that nano-antennas based on unintuitive shapes (i.e., free-form geometries) can significantly outperform more traditional geometries in various metrics, such as maximum transmission or reflection magnitudes, phase coverage, field of view, and spectral bandwidth [283, 284]. When paired with active materials, metasurfaces comprised of unintuitive nanoantenna shapes offer the potential to achieve major

Table 2: Applications of active metasurfaces: green-yellow-red colors indicate decreasing relevance of the metric to the target use case (very important-some what important-not relevant).

Application	Switching contrast (relevant metrics listed)	Optical efficiency	Endurance (cycling lifetime)	Speed	Power consumption
modulation	Extinction ratio		$> 10^{15}$	> 1 GHz	
Spatial light modulation	Cross-talk		10^{10}	0.1-1 kHz	
Beam steering (LIDAR)	Cross-talk		10^{13}	100 kHz	
Tunable filter	Tuning range		10^3	1 kHz	
Adaptive optics	Phase correction coverage		$> 10^9$	> 0.1 kHz	
Lens autofocus	Focal length tuning range		$10^4 - 10^7$	0.1 kHz	
Zoom lens	Zoom ratio & cross-talk		$10^3 - 10^6$	1 Hz	
Holographic display	Color gamut		$10^6 - 10^9$	0.1 kHz	
Reflective display (electronic paper)	Color gamut		$> 10^6$	> 1 Hz	Must be nonvolatile
Dynamic projection display	Color gamut		$> 10^9$	0.1 kHz	
Optical limiter	Extinction ratio		1 - 10	> 1 GHz	
Adaptive thermal camouflage	Emissivity tuning range		$10^4 - 10^9$	1 kHz	

performance boost across multiple functionalities. The number of design variables used to define a metasurface unit cell also impacts the ability to find optimal solutions; unit cells parametrized with fewer variables are easier to explore than those with larger numbers of variables. Therefore, exploration of the significantly expanded free-form design space necessitates advanced optimization tools and inverse-design strategies [283].

Optimization methods for metadvice design are broadly categorized into local, global, and multi-objective strategies. Local and global algorithms differ in their pursuit of function minima: local algorithms generally fall into local minima, while global algorithms attempt to find the true global minimum. In metadvice design, both local and global algorithms are employed to minimize user-defined cost functions which are used to measure the quality of a given design against a set of predetermined performance criteria. These cost functions are generally hyperdimensional, and their input values are limited to finite ranges in order to incorporate constraints related to the chosen fabrication techniques, materials selection, and SWaP (size, weight, and power) considerations.

While ill-suited for problems with many minima, local optimizers have found success in topology optimization of optical nanoantenna and metasurface designs

due to their ability to exploit gradient information generated through adjoint analysis [285–292]. In particular, topologically optimized multifunctional metagratings were shown to realize wavelength-dependent deflection of incident light into predefined diffraction orders [293]. When building large-area, aperiodic metasurfaces, libraries of topology-optimized unit cells can be constructed and arrayed to stitch the output beams together for desired wavefront shaping [294], such as lensing [295]. Furthermore, free-form metasurfaces with dimensions ≥ 100 wavelengths and multiple layers have been realized, yielding multi-angle and multiwavelength metalens designs [296]. Topology optimization's greatest strength is its ability to generate relatively free-form geometries due to its lack of strict unit cell parameterization. Still, topology optimization suffers from the same drawbacks that limit local optimizers, namely, the tendency to get stuck in local minima and the inability to optimize highly multimodal problems.

Global optimization algorithms are largely able to overcome these issues. While nearly countless examples of global optimizers exist today, algorithms such as the genetic algorithm (GA) [297, 298], particle swarm optimization (PSO) [299, 300], and the covariance matrix adaptation evolution strategy (CMA-ES) [301–303] are among the most

popular for optical device optimization [283]. Most global optimizers are population-based evolutionary algorithms which update and adapt a population as they explore a function's response surface to produce new generations better suited to finding the true global minimum. Global optimizers have many advantages over local algorithms, which include forgoing of potentially expensive gradient calculations and applicability to more general and multimodal problems.

Regardless of their specific construction, conventional local and global optimizers generally only seek to optimize a single cost function. Nevertheless, in most cases, engineering problems have multiple competing objectives that designers would like to optimize. With single-objective optimizers (SOOs), the traditional procedure is to include all objectives in a single weighted sum. However, this typically requires *a priori* knowledge of how best to weight the objectives and can actually eliminate portions of the solution space where the optimizer is unable to explore. Moreover, SOO algorithms yield only a single solution and provide no additional information to the user as to how to judge the design objective tradeoffs inherent to the system. In contrast, multi-objective optimizers (MOOs) such as NSGA-III [304], multi-objective CMA-ES [305], and Borg [306] are able to globally optimize problems with multiple competing cost functions [307]. Furthermore, they produce a collection of solutions called the Pareto set, which contains information about the inherent tradeoffs between design objectives. Finally, it has been shown that optimization is crucially important to maximizing the performance of multifunctional metadevices [205, 308]. To this end, MOO algorithms are ideally suited to this task and form the basis of the proposed reconfigurable metasurface inverse-design process. In Section 7, we show exemplary reconfigurable metasurfaces based on O-PCMs using such optimization approaches.

In addition to optimization techniques, machine learning (ML)-based design methods have emerged as a computationally efficient solution to exploring large design spaces in nanophotonic devices [309–313]. One should first collect training data, which contains sets of nanophotonic structures and their respective electromagnetic (EM) responses extracted from full-wave simulations. Then, a neural network (NN) is trained with that data to establish correlations between the parameters and attributes. Once appropriately trained, the NN can perform accurate and rapid prediction of EM responses of a given nanostructure, or inversely, it can search for the design parameters corresponding to the desired response. Therefore, this method enables efficient nanophotonic device evaluation and its design prediction. Overall, ML-assisted design approaches

have already shown promising progress in developing a variety of high-performance metasurfaces [310, 314–318].

Due to the immense DOFs in constructing metasurfaces, early demonstrations using traditional NNs are restricted by the initial training sets with limited geometrical parameters. Generative adversarial network (GAN) methods, which are based on a self-evolving critic evaluating generated designs, allow efficient creation of arbitrary design patterns [319–323]. Such techniques customized for specific electromagnetic processes with complex meta-atom geometries have also been developed [324–328]. In the study by Jiang and Fan [324], adjoint variable calculations were incorporated into generative NNs to produce topology-optimized structures through a global search.

When applied to active elements, the ML-assisted approaches were demonstrated to generate efficient designs of multifunctional and reconfigurable metadevices [316, 323, 325]. Encountered by the dramatically enlarged DOFs and associated uncertainties, design constraining rules, which take into account experimental imperfections, have been incorporated in several design frameworks to enhance their robustness [316, 317, 320]. In Section 7, we illustrate the use of ML methods to blueprint multifunctional active metadevice designs based on O-PCMs.

6 Active metadevice design and fabrication: general principles and case studies

The subwavelength pixelated device architecture and capability of on-demand control in principle allow nearly arbitrary wavefront-tuning functionality. In this section, we will focus on nonmechanical active metasurfaces, in which tuning is attained via refractive index change in the material composing meta-atoms.

The operation principles of nonmechanical active metasurfaces can be generally categorized into two groups: individual meta-atom tuning and collective metasurface tuning. The individual meta-atom tuning approach, schematically illustrated in Figure 1a, simplifies unit cell designs by leveraging additional DOFs from the switching matrix. Moreover, individual meta-atom modulation in principle enables arbitrary and continuously tunable optical functions for a single device. However, scalable electrical control of individual meta-atoms remains a major challenge for switching large-area 2-D meta-atom arrays. Alternatively, instantaneous switching of metasurface patches (schematically illustrated in Figure 1b) considerably simplifies the control

Figure 1: Basic design principles of reconfigurable metadevices: (a) individual meta-atom tuning; (b) collective metasurface tuning. Red and blue colors indicate different optical states of the meta-atoms upon external stimulation.

process. However, the collective modulation scheme, in general, can only achieve switching between a discrete set of states with predefined, albeit arbitrary, optical functions. One embodiment of this approach is to mix meta-atom subarrays designed for different functions on the same aperture region and selectively turn on/off part of the array to allow optical function switching [190]. This “shared aperture” approach, while being straightforward to design and implement, suffers from limitations on optical efficiency and scalability of optical functionalities due to spatial division of the aperture.

In this section, we focus on a generic design method enabling full-aperture active phase-gradient metasurfaces via collective tuning: the meta-atoms are individually designed to achieve distinctly variable optical responses upon external stimulations. When switched under a single control signal, collectively they provide variable optical functionalities utilizing the full metasurface aperture. This approach allows the most straightforward control mode, since only one tuning signal is required for each state, but meanwhile, this method requires judiciously designed unit cells and device architectures. Here, we use O-PCM-based all-dielectric metasurfaces to exemplify the design process, strategies and challenges, which cover the essential stages of developing reconfigurable metasurfaces spanning device design, fabrication, calibration, and operation. **We note that the design principle is generic and can be applied across all the nonmechanical active metasurface platforms discussed in Section 2.**

6.1 O-PCM-based meta-atom modulation: an overview

O-PCMs can be used as either a blanket layer to trigger the mode transitions in metallic structures resting upon them [178, 329–331] or the building materials of meta-atoms which modulate the transitions directly [175, 332]. In the study by Chen et al [333], a tunable resonator composed of a gold nanodisk array placed on a GST thin layer was

designed and experimentally verified. As shown in Figure 2a, dimensions and periodicity of the gold nanodisks, together with the thickness of the GST layer, were carefully chosen to achieve a significant resonance shift in the near IR. This resonance shift enabled a large modulation of the transmitted light intensity of around 50% at 2.4- μm wavelength. Apart from GST, this modulation approach can also be achieved with other materials, such as VO_2 . In the study by Peng et al [329], a subwavelength gold grating array was deposited on a VO_2 film coated on a glass substrate to realize a reconfigurable polarizer (Figure 2b). To maximize the switching efficiency, the transmission properties of the structures were studied through a complete exploration of the parameter scope including the gap g between the gratings, the duty cycle w/p , the height h of the gratings, and the thickness of the VO_2 thin film. After an optimal parameter combination was found during the parameter sweep, the high transmission contrast between transverse electric (TE) and transverse magnetic (TM) incidence can be explained by the electric field dissipation behavior revealed by the simulation results.

When O-PCMs are used as the building materials of meta-atoms, different multipole resonances can be excited inside the material during the structural transition, which in turn can be utilized to modulate the amplitude and phase of the incident light. Several works have realized optical reconfiguration based on pure amplitude modulations. In the study by Wang et al [334], through harnessing reflection and transmission resonances at specific wavelengths, reconfigurable devices such as multifocus Fresnel zone plates, lenses, and grayscale holograms can be achieved by writing, erasing, and rewriting 2-D binary or grayscale patterns on a GST canvas. More specifically, a continuous relative change of reflectance up to 100% was achieved using excitation laser pulses. In addition to the optical transmission control, Zou et al [335] showed that the structural transition of GST in patch antennas can also trigger continuous phase-shift modulations. In both nanoantenna types shown in

Figure 2: Modulation of phase-change/transition material-based meta-atoms: (a) Illustration of a hybrid phase-change plasmonic crystal realized as an array of gold nanodisks on a GST film [333]. (b) Diagram of a linear polarizer consisting of gold gratings deposited on a VO_2 film [329]. The geometrical parameters were optimized to achieve the highest switching efficiency and extinction ratio. (c) Drawing depicting two types of patch nanoantennas and their corresponding phase-shift ranges [326]. (d) Top: schematic of a tunable GST nanorod placed on top of a gold substrate. Bottom: maps of phase shifts vs. width and length of GST nanorods in amorphous and crystalline states [332]. GST, Ge–Sb–Te.

Figure 2c which consist of a silver patch placed on GST, continuous phase modulation up to 2π can be achieved by tuning the length of the silver patches. Similarly, Chu et al [332] employed two distinct meta-atoms to augment the phase coverage. The optical structure proposed in this paper consisted of rectangular-shaped GST nanorods placed on a gold mirror with a spacer layer (Figure 2d). A complete parameter sweep of length and width of the GST rods were carried out to find the geometry that yields the largest phase shift of 120° under two different states, respectively. It should be noted that the works described above mostly used parameter sweeping to identify the optimal designs, while strategies on determining other key dimensions such as dielectric layer thickness or period were not mentioned. In Section 7, we outline the limitations of using this prevailing unit cell-searching method and discuss more advanced meta-atom design approaches.

6.2 Metasurface synthetization

Here we discuss the design method of constructing phase-profile reconfigurable metasurface optics via collective tuning. We use a varifocal metalens operating at $5.2\text{-}\mu\text{m}$ wavelength as an example to illustrate the design procedure (Figure 3a), while the same design principle can be adopted for tuning between arbitrary functionalities via wavefront engineering. Key device performance metrics are optical efficiency, contrast ratio, and imaging quality at different optical states. This generic design approach can be used for a variety of meta-atom platforms across different spectral ranges. Assuming N is the number of

phase levels covering the 2π phase range and M is the number of switchable metadvice states, then one would need N^M distinct meta-atom designs to realize M arbitrary functionalities. In the simplest-case example, two phase levels (i.e., 0° and 180°) are used to sample the 2π phase range; a larger number of phase levels are expected to increase the optical efficiency [9]. For transitioning between the two states (e.g., amorphous and crystalline states of the O-PCM), the metasurface design requires a library of four meta-atoms. Each of the selected meta-atoms provides a distinct combination of two phase values corresponding to the O-PCM states. The selected meta-atoms are then subsequently assembled into a 2-D array to generate the desired phase profiles. The meta-atoms are implemented as all-dielectric Huygens resonators, which feature an ultrathin, deep subwavelength profile that facilitates a simple one-step etching fabrication process [336]. Other types of metasurfaces (e.g., truncated waveguide or geometric-phase antenna) can be utilized as well using the same design framework. GSST was selected as the building block material due to its broadband transparency, large refractive index ($n = 3.2\text{--}4.7$), and large index contrast during phase transition ($\Delta n \sim 1.5$ at $5.2\text{-}\mu\text{m}$). CaF_2 was chosen as substrate material due to its high IR transparency.

In the case of a varifocal metalens, one could first generate hyperbolic phase profiles for the two specified focal lengths by using the following equation [10]:

$$\phi = \frac{2\pi}{\lambda_0} \left(\sqrt{f^2 + x^2 + y^2} - f \right) \quad (1)$$

where λ_0 is the wavelength of the incident light, x and y are the coordinates of meta-atoms, and f is the focal length of

Figure 3: (a) Schematic drawing of a varifocal metalens based on O-PCMs. (b) Ideal hyperbolic phase profiles designed for two focal lengths at different material states. (c) Two-dimensional discretized phase masks at amorphous (left) and crystalline (right) states. Two phase levels, 0° (colored white) and 180° (colored black), are used to sample the 2π phase range. O-PCMs, optical phase-change materials.

the metalens at a certain state. The total size of the phase profiles was $1 \times 1 \text{ mm}^2$, and they were designed to exhibit aberration-free focusing at the focal lengths of $f_1 = 1 \text{ mm}$ and $f_2 = 1.5 \text{ mm}$ for amorphous and crystalline states, respectively. The ideal hyperbolic phase profiles are shown in Figure 3b. The two continuous phase profiles were then discretized in the spatial domain according to the meta-atom arrangement (i.e., with a lattice constant of approximately $\lambda_0/2$) and in the phase domain into multiple phase levels.

The reconfigurable metalens was designed and modeled utilizing a hierarchical combination of full-wave simulations and Kirchhoff diffraction integral. At the subwavelength scale, full-wave simulations can be implemented to design and model the meta-atoms. With a GSST thickness of $1 \mu\text{m}$, a pool of Huygens meta-atoms

with various shapes (such as “I” and “+” shapes) were generated in a commercially available full-wave electromagnetic solver (CST Microwave Studio), and a group of four meta-atom structures were chosen based on their phase and amplitude responses at both states (Figure 4a,b). The meta-atoms were designed and generated in compliance with certain design constraints, such as minimum and maximum feature sizes, rounded corners, fabrication tolerance, etc. At the macroscopic level, phase masks were designed and verified using the Kirchhoff integral method to evaluate the metalens performance. Such a model can be further combined with performance figure of merits (FOMs) to guide the selection of meta-atoms and constructing metasurfaces with enhanced optical contrast and efficiencies for the two states, as detailed in the study by Shalaginov et al [192].

Figure 4: (a) Top view of a group of four GSST Huygens meta-atoms covering 2π phase shift. (b) Each meta-atom provides a distinct combination of the two phase levels close to 0° and 180° in both states. Cross-sectional plots of focal plane optical intensity simulated using the Kirchhoff integral method at (c) amorphous and (d) crystalline states. Sensitivity study of metalens performance (focusing efficiency and contrast ratio) dependence on (e) refractive index variance (Δn) and (f) meta-atom thickness variance (Δt_{GSST}). GSST, $\text{Ge}_2\text{Sb}_2\text{Se}_4\text{Te}_1$.

The diffraction integral method incorporating the full-wave simulation data enables computationally efficient validation of the optical performance of the entire metalens [336].

We modeled the metalens response by using the diffraction integral method and plotted the cross sections of the optical intensities in focal planes 1 and 2 designed for the amorphous and crystalline states, respectively (Figure 4c,d). For comparison, we added the optical intensity curve of the ideal diffraction-limited lens having the same optical parameters. The metalens performance metrics, including focusing efficiency and contrast ratio, are summarized in Figure 4e,f. For the primary focal spots, the focusing efficiencies for amorphous and crystalline states were 27.1 and 24.3%, respectively. The efficiencies are defined as the ratio of the power confined within a radius of $5\lambda_0$ to the total power incident on the lens aperture. In contrast to passive meta-optics, the performance of reconfigurable metadevices is further weighted by cross talk across different states. This results in the appearance of phantom images, which are formed by the additional “erroneous” focal spots, and should always be minimized. Cross talk can be quantified by switching contrast ratio (CR) between the two states:

$$CR = 10 \log_{10} \left(\frac{P_{1,a}}{P_{2,a}} \cdot \frac{P_{2,c}}{P_{1,c}} \right) \quad (\text{in dB}) \quad (2)$$

where $P_{1(2),a(c)}$ denotes the focused optical power at focal plane 1 (2) at the amorphous (crystalline) state. The simulation shows a CR of 32.2 dB, indicating negligible cross talk. Another important lens characteristic is the Strehl ratio, which is defined as the ratio of the peak intensity of an evaluated point spread function (PSF) to the peak intensity of a diffraction-limited PSF for an ideal, aberration-free optical system. The Strehl ratios for our varifocal metalens exceed the 0.8 threshold in both states, hence confirming that the metalens operates in the diffraction-limited regime.

The simulation results are consistent with theoretical diffraction efficiency limits of multilevel diffractive optical elements [337] and can be explained by examining the average phase errors and transmittance of the meta-atom group (shown in Table 3). The average phase errors are estimated by subtracting the ideal phase masks from the actual ones and averaging the phase deviations. Since the selected meta-atoms provide phase values at approximately 0° or 180° , any target phase value between 0° and 360° can be sampled using these two phase levels with an averaged error of approximately 45° . Theoretically such a phase sampling accuracy results in maximum diffraction efficiency of about 41%, assuming unity optical

Table 3: Simulated focusing efficiency, averaged phase errors, and meta-atom transmittance of the bistate varifocal metalens with two phase levels.

	Amorphous state		Crystalline state	
	Focusing eff.	Phase error (avg.)	Focusing eff.	Phase error (avg.)
Focal plane 1	27.1%	44.8°	2%	92.4°
Focal plane 2	0.2%	91.9°	24.3%	45.8°
Avg. meta-atom eff.	67.6%		64.6%	
Strehl ratio	Close to unity			

transmittance of the meta-atoms [337]. On the other hand, the averaged transmittances of the meta-atoms used to assemble the metasurface are 64.6 and 67.6% for the two states. The theoretically predicted focusing efficiencies of 27.7 and 26.5%, calculated as the products of the diffraction efficiency and the average meta-atom transmittance values, are in excellent agreement with the numerical simulation results. To further improve the optical efficiencies, one can increase the number of phase levels (e.g., 4 and 8 phase levels correspond to 81 and 94.9% maximum diffraction efficiencies, respectively); meanwhile, the overall meta-atom transmittance can be further enhanced.

6.3 Calibration: bridging the gap between numerical models and experimental implementations

Once an initial metasurface design is obtained, a calibration step is essential to identify deviations between the design and fabricated structures. The deviations typically arise from meta-atom geometry and refraction index differences from the assumed values in the model. Here we perform a sensitivity study to illustrate the impact of such deviations by introducing refractive index and thickness variances ($\Delta n = \pm 0.1$ and $\Delta T = \pm 0.1 \mu\text{m}$, respectively) to the numerical models of the varifocal metalens. The simulation results are summarized in Figure 4e,f. The optical responses (both amplitude and phase) of the Huygens meta-atoms exhibit strong dependence upon such disturbances due to the locally induced resonance shifts at both amorphous and crystalline states, resulting in up to ~ 60 and $\sim 55\%$ relative reduction on metalens focusing efficiency and contrast ratio (in dB). In particular, phase deviations not only reduce diffraction efficiencies but also exacerbate cross talk between the two states. Therefore, to fully account for the impact of such imperfections, it is important to quantify the deviations of meta-atom geometry and material optical properties from the design model values.

The meta-atom geometry deviation usually originates from the material deposition and lithographic patterning process. The typically observed fabrication imperfections are thickness variance, angled sidewalls, surface roughness, edge rounding, etc. To quantify such deviations, we calibrated the metasurface design by importing the “as-fabricated” geometries into the numerical models. Shapes and, subsequently, the contour profiles of the fabricated meta-atoms were retrieved from scanning electron microscope (SEM) images. As illustrated in Figure 5a–d, the original top-view SEM image was processed using image processing tools to extract contour profiles of the top and bottom of the meta-atoms. Additional details can be retrieved from the angled SEM images (Figure 5e) to reconstruct 3-D geometries fully resembling the fabricated meta-atoms (see Figure 5f). The 3-D “as-fabricated” model incorporating all geometric deviations was subsequently fed back to full-wave simulation tools to re-evaluate and optimize their optical responses. Consequently, the geometric mismatch between design and fabrication can be effectively minimized to realize metasurfaces with “as-planned” functionalities and sufficient tolerance to imperfections.

Another source of potential deviation between the numerical model and experimental results is the refractive

index and its dispersion in fabricated devices. In an exemplary calibration protocol, the film thickness is first measured using a stylus profilometer. Then the precalibrated film is patterned and fabricated into periodic arrays of nanodisk antennas with various diameters. These antennas are designed to produce distinct resonances, which originate from the excitation of multipole modes inside the dielectric nanodisks. Using a commercial spectrophotometer setup, the transmittance spectra are subsequently measured and fitted with the simulated data, where the refractive index is adjusted so that the simulations match well the experimental results. The same calibration procedure can be performed for samples under different states.

7 Implementation of advanced design and optimization approaches

In the example discussed in Section 6, we adopted a traditional parameter sweeping approach to identify the active meta-atom design. Building a meta-atom library for such multistate metasurfaces poses a multi-objective

Figure 5: Generation of 3-D meta-atom geometry from scanning electron microscope (SEM) images of fabricated samples. (a) SEM top-view image of an exemplary meta-atom. (b) Image processing technique to identify the possible boundaries. (c) Subsequent extraction of the bottom contour. (d) Binary image of the meta-atom cross section. (e) Angled-view SEM micrograph depicting the sidewall shape. (f) Three-dimensional geometry resembling the as-fabricated meta-atom.

optimization challenge which is far more difficult than constructing a passive metasurface design. Additionally, the number of meta-atoms needed increases exponentially with the number of states. In reality, the accessibility of optimal meta-atoms may be limited by the pool of candidates obtained from full-wave simulations. These difficulties render the traditional parameter sweeping approach highly inadequate. In this section, we will discuss the implementation of advanced meta-atom design and searching methods to accelerate and improve the design process.

7.1 Multi-objective optimization for reconfigurable metasurface synthesis

In this section, a multi-objective optimization enabled design framework is proposed for the efficient generation of multifunctional meta-atoms based on O-PCMs. Two exemplary reconfigurable dielectric metasurface devices are then presented in order to advocate the efficacy of the proposed optimization framework. Importantly, while here we choose O-PCM-based active metasurfaces to illustrate the optimization process, these algorithms are broadly applicable to other tuning mechanisms summarized in Table 1 that modulate the optical responses of meta-atoms.

As discussed in Section 5, MOO algorithms are ideally suited to the design tasks of multifunctional metadevices, an overview of which can be found in Figure 6. The goal of

the proposed inverse-design and optimization process is to synthesize reconfigurable metasurfaces either directly, if time permits and sufficient computational resources exist, or, more commonly, through the generation of a “periodic table” of meta-atoms which can later be aperiodically tiled to form a complete metasurface. The process begins with the initialization of the optimizer, which generates an initial set of candidate meta-atoms to simulate. The next step is to enforce several, or all design constraints (e.g., minimum feature size, radius of curvature, etc.), and alter the meta-atom geometries accordingly. For simplicity and speed of simulation, meta-atoms are then evaluated under plane wave illumination with doubly periodic boundary conditions which mimic their behavior in an infinite array. Next, data (e.g., complex transmission and reflection coefficients) are gathered from the simulations and are used to evaluate a set of predetermined cost functions which the optimizer seeks to minimize. The values generated by the cost functions are then used to evaluate end (stopping) condition (e.g., maximum allowed function evaluations or other convergence criteria). Finally, data are fed back to the optimizer and the process repeats until the end condition is met. When the process is finished, a Pareto set of solutions is generated, which in the hypothetical example shown in Figure 6 showcases the tradeoffs between the performances achievable at binary states of the O-PCM. Finally, these solutions are used to populate the periodic table of elements.

Figure 6: Flowchart showing the multi-objective optimization-powered process for synthesizing multifunctional metasurfaces based on O-PCMs. Once the (left) optimization process is complete, a set of solutions (middle) is presented to the user. The blue dots represent feasible designs while the purple, red, and green dots represent Pareto optimal designs. All of these designs can be used to generate a periodic table of elements (right top) which form the basis for synthesizing a complete metasurface (bottom right). O-PCMs, optical phase-change materials.

As previously discussed, the performance achievable by the optimized meta-atoms is highly dependent on what geometrical inclusions they can assume. While topology optimization is an attractive option for generating unintuitive meta-atom shapes, it is challenging to pair it with global optimization algorithms. Nevertheless, the ability to generate relatively free-form geometries, while simultaneously exploiting the global robustness and multi-objective support afforded to us by state-of-the-art optimizers, is highly desired. To this end, we employ a level-set method based on Bèzier surfaces, which has been shown to offer extraordinary geometrical flexibility while only requiring a few variables to define the surface [338]. Moreover, these surfaces are readily optimizable with global and multi-objective algorithms, making them an ideal choice for generating reconfigurable and multifunctional meta-atoms. An overview of the meta-atom generation process is provided in Figure 7. The generated 3-D control surface is first converted to a binary representation to determine the meta-atom borders. These 2-D outlines are then vertically extruded to realize initial 3-D shapes. Next, predefined fabrication constraints can be enforced. The sharp corners of the original design are rounded to meet some hypothetical fabrication specification while yielding the added benefit of removing areas that may produce significant field enhancements. Additional constraints can then be employed to leave only the largest island and further eliminate narrow areas. These geometrical alterations can be applied via a combination of simple matrix

manipulations and image processing techniques before extrusion.

The proposed optimization framework is general enough to be applied to a tremendous variety of multifunctional and reconfigurable metasurface problems. To test the efficacy of the proposed framework, two exemplary reconfigurable metasurface-based devices are presented further, along with thorough discussions of the optimization and performance results.

7.2 Exemplary reconfigurable dielectric meta-optic design based on O-PCMs

Perhaps the most exciting aspect of optical nanoantennas is their ability to offer simultaneous control over amplitude and phase (and polarization) [339]. In traditional optical devices, one normally would not want to tune the amplitude since that always means a decrease in the transmitted power which can negatively affect system performance. However, in reconfigurable metasurfaces, control over both amplitude and phase is extremely desirable. For example, one could design a metadvice to have large transmission or reflection in one state and no transmission or reflection in another. Also, a device could be synthesized to switch from transmitting to reflecting modes or provide on-demand tunable beam-steering capability.

We first take GST, the classical O-PCM, as an example. In the study by Pogrebnikov et al [205], a meta-atom was developed using a genetic algorithm to achieve high transmission when the GST was in its amorphous state and high absorption in its crystalline state. Using the material data from the study by Pogrebnikov et al [205], the proposed multi-objective optimization framework was employed to generate an unintuitive unit cell with the same objectives, albeit with a different periodicity and material thickness and for a wavelength of $1.55\ \mu\text{m}$. The unit cell was illuminated with a linearly polarized plane wave normally incident from the top (air side). The period was set to be $800\ \text{nm}$ and the thickness $250\ \text{nm}$. The refractive indices of the constituent materials at $1.55\ \mu\text{m}$ were 1.444 for SiO_2 as well as $4.164 + 0.140i$ and $7.722 + 2.271i$ for GST in its amorphous and crystalline states, respectively. The GST layer patterning was generated using the proposed design method with 5×5 uniformly spaced control points while enforcing fourfold symmetry and optimized using a state-of-the-art multi-objective optimizer, Borg [306], with two objectives: maximizing (1) amorphous state transmission and (2) crystalline state absorption. Figure 8 shows the optimization results. Each circle represents a different meta-atom geometry

Figure 7: Meta-atom generation process: (top left) a Bèzier control surface which is intersected by a level-set plane to determine the meta-atom border, (bottom left) extruded 3-D meta-atom, (top right) initial application of fabrication constraints to remove sharp corners, and (bottom right) application of additional constraints to remove small islands.

simulated with a full-wave Maxwell solver employing doubly periodic boundary conditions. Looking at Figure 8, the ideal solution would be a dark blue circle in the top right corner, which would correspond to a design that achieves complete transmission and absorption in the amorphous and crystalline state, respectively. However, due to losses in the amorphous state and unwanted reflection/transmission in the crystalline state, this ideal solution is unattainable. Fortunately, as one can see, there is a range of solutions that nearly achieve this goal with differing amounts of tradeoff between the two objectives. Note that higher transmittance values in the amorphous state leads to a reduction of crystalline state absorption. These designs (near the bottom right of the figure) contain very little GST material which is the cause of their low loss values. If one wants to minimize the power transmitted in the crystalline state (blue color), then one must accept a slight reduction in the maximum transmittance in the amorphous state. From Figure 8, one can see that the transmittance achieved in the crystalline state can be quite low (dark blue), indicating a very strong spectral filtering effect in this reconfigurable device.

From the data set shown in Figure 8, one of the best performing designs was selected for further examination. Figure 9 summarizes the reflectance, transmittance, and absorption of a homogeneous GST slab on an infinite SiO_2 substrate and compares it to that of the optimized metasurface unit cell. Both simulations were performed using COMSOL Multiphysics v5.3 [340]. One sees that the optimized design achieves a significant enhancement in the absorption magnitude through intelligent patterning of

GST. This confirms that the optimized design enhances the intrinsic behaviors of GST in both states. Interestingly, while the homogeneous GST slab is highly reflective due to its large refractive index, the patterned-GST layer has a very low reflection in both states. However, in the amorphous state, the loss is significantly less than in the crystalline state, which is why the transmission and absorption are so pronounced in these states, respectively. In the amorphous state, the optimized unit cell achieves broad transmission behavior while the crystalline state has a broad absorption behavior with very low transmission. Such a device could be used as an optical switch, a nonmechanical shutter or a spectral filter in an imaging system.

The proposed MOO framework can also be employed to efficiently generate a periodic table of meta-atoms that each offer a unique optical response. The elements of this periodic table can then be used as building blocks to synthesize complete metasurfaces. Diffraction efficiency measures the percentage of incident power the metasurface can steer into a desired transmitted or reflected diffraction order and is an important metric to judge metasurface performance. To this end, dielectric metasurfaces are extremely desirable for their low loss [341], which can be exploited to achieve very high diffraction efficiency [342]. As discussed earlier, reconfigurable meta-optics using traditional O-PCMs, such as GST, are inherently limited by high material absorption losses. Fortunately, another O-PCM GSST offers a large refractive index change when switching from the amorphous to crystalline states, while still maintaining low loss [211, 343]. The reduced loss makes GSST an enticing material option for high-efficiency transmissive and reflective reconfigurable metasurfaces [192].

In the second example, we design a GSST reconfigurable phase-gradient metasurface operating at $5.2\text{-}\mu\text{m}$ wavelength. As a first step, a multi-objective optimization was carried out to find the best performing meta-atoms in both states of GSST. The meta-atoms were simulated at a design wavelength of $5.2\text{-}\mu\text{m}$ and with a period of $2.548\text{-}\mu\text{m}$. A normally incident linearly polarized plane wave illumination was imposed on the GSST layer from the top. The unit cell was comprised of a $1\text{-}\mu\text{m}$ GSST layer on top of a 200-nm platinum layer with permittivity $\epsilon_r = -409.96 + 178.69i$ [344]. The thick platinum layer effectively serves as a ground plane to prevent transmission and is electrically heated to change the GSST material state. The GSST permittivity is $\epsilon_r = 12.16 + 0.1213i$ and $\epsilon_r = 19.03 + 0.1658i$ in the amorphous and crystalline states, respectively. As in the previous example, the meta-atom designs were created using the synthesis methods described above.

The data shown in Figure 10 indicate that a tremendous variety of solutions exist owing to the low loss and

large tunability of GSST. Each dot represents a unique meta-atom geometry, and the dot color represents the reflectance in the amorphous and crystalline states (Figure 10a,b), respectively. Since the purpose of this

design is to achieve a high-reflection-efficiency reconfigurable metadvice, the dots with the highest reflection magnitudes are plotted on top of other designs. It should be noted that in both states, there exist meta-atom geometries

that achieve a range of reflection magnitudes in addition to reflection phases. The goal in designing these meta-atoms is to create a reconfigurable beam-steering metasurface where, in the amorphous state, the incident light is reflected into the -1 diffraction order, and in the crystalline state, the light is normally reflected (0th order).

To synthesize the beam-steering device, only geometries that achieve large reflection magnitudes in both states are considered. The meta-atoms were chosen to achieve a linear phase gradient in the amorphous state while simultaneously maintaining a fixed reflection phase in the crystalline state. The chosen meta-atoms were combined into a supercell (see Figure 11a) whose x - and y -periods are 7.644 and 2.548 μm , respectively. The synthesized design achieved diffraction efficiencies of 72.2 and 79.9% in the -1 and 0 diffraction orders for the amorphous and crystalline states, respectively (Figure 11b). The reflectarray design also exhibits high contrast ratio of 23 dB. The ripple in the reflected waves seen in Figure 11c is due to the presence of minor contributions from the other undesired diffraction orders. These results serve to demonstrate the power of the proposed reconfigurable metasurface framework.

7.3 Multifunctional meta-atoms design using deep neural networks (DNNs)

As discussed earlier, building a meta-atom library serving multistate metasurface designs is significantly more

challenging than performing the same task for a passive metasurface. The extra complexity arises from the need to fulfill multiple design objectives, thereby demanding an exponentially increased number of meta-atoms. Additionally, the requirements for phase and amplitude precision, as well as tolerance to fabrication and operation deviations, become even more stringent in order to avoid cross talk and efficiency reduction during the state transition. While the MOO techniques enable the exploration of significantly expanded design spaces, it is also highly desirable to develop design generation and validation tools in place of full-wave electromagnetic modeling to complement the optimization algorithms and enhance the design throughput.

A recently emerged DNN-based metasurface design and characterization approach [316, 323, 328] offers a promising solution to address the design throughput challenge. In the study by An et al [316], an all-dielectric reconfigurable meta-atom design based on NNs was presented. After training with data, the meta-atom performance predicting NNs can rapidly evaluate phase and amplitude responses of nanodisks of various radii, heights, periods, and refractive indices over a broad spectral band. A closed-loop NN, illustrated in Figure 12a, was constructed to generate meta-atom designs with on-demand optical responses. In this NN, the model generator produces a meta-atom structure, which is then fed to the predicting neural network to assess their amplitude and phase responses. The response data are then

sent back to the model generator, where a new meta-atom structure is produced with the goal of reducing the difference between the current and the desired meta-atom responses. The process reiterates until a satisfactory meta-atom design is reached. The model generator can be readily modified to meet diverse design requirements. By leveraging this design framework, a cylinder-shaped meta-atom structure yielding over 310° phase coverage, while its refractive index continuously varies from 3.5 to 4.5, was obtained within several minutes of computation time (Figure 12b). With conventional approaches, convergence to similar designs would require intensive parameter sweeping and elaborate field distribution analysis, which can easily take hours or days [345].

Reconfigurable meta-atom designs are usually composed of simple canonical shapes, such as cylinders [333], bars [329, 335], and gratings [187, 329], which have a narrow space of variable design parameters leading to limited metadvice performance. Fortunately, NN approach incorporating GANs can dramatically increase the design DOFs by exploring free-form meta-atom geometries. A recent paper discusses the possibility of using GANs to produce free-form all-dielectric multifunctional meta-atoms and entire metadevices [323]. As a demonstration, this method was tested on the design of a polarization-multiplexed bifocal lens (Figure 12c), whose performance was further verified with full-wave simulations. By using the training data, including phase and amplitude responses of meta-atoms at different material states, a reconfigurable meta-atom design network can be constructed based on this framework. This novel approach is extremely time-efficient (i.e., on-demand meta-atoms can be produced within milliseconds) and allows exploration of numerous design degrees of free-form with meta-atom geometries. We envision that this approach will empower the process of designing metasurfaces, especially those with multifunctional and reconfigurable features.

8 Outlook

As we have elaborated in this review, active metasurfaces have taken major strides over the past decade, and the technology is maturing to the point where it is ready to make an impact on practical applications. Indeed, in very recent years, several startup companies such as Tunoptix [346] and Lumotive [347] have emerged seeking to commercialize various active metasurface technologies, a growing trend we will likely witness in the near future. It,

therefore, comes as no surprise that the research emphasis in the area is starting to transition from exploring different optical modulation mechanisms to perfecting the meta-optics performance such that they can start to compete with and even topple their traditional bulk counterparts. This paradigm shift prompts the organization of our discussions herein and the O-PCM metasurface design example, through which we aim to highlight the useful techniques in optical engineers' toolbox for developing active meta-optics with high optical quality.

Besides optical quality, scalability is another key challenge that must be addressed for active metasurfaces. In many examples of active metasurfaces cited here, the optics were demonstrated with apertures of the order of tens of microns or even smaller. Scaling to much larger areas (mm to cm scale), which are the norm for most practical optical systems, is important for two reasons. First, the optical performance measured on small-aperture optics might not be representative of the same design with larger apertures. This is in part because fabrication nonuniformity is often exacerbated with large areas, and in part, because optical aberrations also scale with increasing aperture size in optical systems where systematic deviations from the ideal diffraction-limited phase profiles are present. Additionally, large aperture size also presents a hurdle toward **electrical** addressing of meta-atoms, which is probably the preferred active tuning scheme for many practical applications. The collective switching scheme illustrated in Figure 1a faces possible challenges associated with large-area uniformity and multistate tuning, whereas the individual meta-atom addressing scheme (Figure 1b) is hardly practical given the extremely large number of meta-atoms (easily exceeding 10^8) in macroscopically sized optics. The subwavelength meta-atom pitch and large array size may further pose stringent requirements on (electrical or thermal) cross talk suppression. We, therefore, anticipate that the solution may entail some "hybrid" switching configurations combining features from both schemes – offering adequate spatial granularity to facilitate continuous or quasi-continuous multistate tuning while leverages collective switching of groups of meta-atoms to mitigate the electrical addressing complexity. Specifically, the symmetry of the optics can be harnessed to minimize the number of independent electrical controls. For instance, a varifocal metalens with continuously variable focal length can be realized by modulating meta-atoms grouped on a series of concentric ring-shaped electrodes given circular

Figure 12: Multifunctional meta-atom design using deep neural networks (DNNs). (a) Schematic illustrating the process of meta-atom design generation by employing predictive neural networks [316]. (b) Top: transmission amplitude and phase responses of cylinder-shaped all-dielectric meta-atoms in the continuous range of material states ($n = 3.5\text{--}4.5$) at $5.2\text{-}\mu\text{m}$ wavelength. Bottom: diagram of electric (arrows) and magnetic (color coded) fields inside the meta-atom in the states #1 and #4 (indicated on the polar plot above). Incident light propagation direction is marked with an orange arrow [316]. (c) Artistic rendering and layout of a polarization-multiplexed, transmissive bifocal lens designed with DNNs [323]. Focal lengths for x-polarized and y-polarized incidences are 80 and 60 μm , respectively. A quarter of the metalens layout is shown at the bottom, where the yellow areas correspond to the dielectric meta-atoms.

symmetry of the lens. An alternative strategy involves mapping the optical functions into two orthogonal directions. As an example, a 2-D metalens can be synthesized from two orthogonally arranged 1-D cylindrical metalenses with considerably reduced electrical routing complexity.

Finally, performance consistency, integration compatibility, and manufacturability are among other important metrics that researchers should strive to improve to enable active metasurface technologies that will make a tangible impact on practical applications.

9 Conclusion

Active metasurfaces possessing a flat, pixelated device architecture enable local and global optical response tuning, thus introducing new opportunities for dynamic wavefront control. In this review, we survey recent progress in reconfigurable metasurface optics, which covers tuning mechanisms, material platforms, and design approaches. We outline key device metrics and review outstanding questions and gaps. Using O-PCM-based active metasurface as an example, we outline a generic design principle for all-dielectric, collectively tuned, reconfigurable metasurfaces. Advanced unit cell optimization tools and design approaches are also discussed to address the escalating design complexity with active metasurfaces. The multiscale, multiphysics, and multi-objective wholistic design framework presented herein is expected to inspire new designs enabling meta-optical devices with unprecedented optical quality, and expedite their deployment in practical reconfigurable optical systems.
