Abstract

Diabetes is a noncommunicable disease and arguably represents the greatest pandemic in human history. Diabetic kidney disease (DKD) is seen in both type 1 and type 2 diabetes and can be detected in up to 30–50% of diabetic subjects. DKD is a progressive chronic kidney disease (CKD) and is a leading cause of mortality and morbidity in patients with diabetes. Renal fibrosis and inflammation are the major pathological features of DKD. There are a large number of independent and overlapping profibrotic and pro-inflammatory pathways involved in the pathogenesis and progression of DKD. Among these pathways, the transforming growth factor-β (TGF-β) pathway plays a key pathological role by promoting fibrosis. Sirtuin-1 (SIRT1) is a protein deacetylase that has been shown to be renoprotective with an anti-inflammatory effect. It is postulated that a reduction in renal SIRT1 levels could play a key role in the pathogenesis of DKD and that restoration of SIRT1 will attenuate DKD. Cell division autoantigen 1 (CDA1) synergistically enhances the profibrotic effect of TGF-β in DKD by regulating the expression of the TGF-β type I receptor (TβRI). CDA1 has also been found to be an inhibitor of SIRT1 in the DNA damage response. Indeed, targeting CDA1 in experimental DKD not only attenuates diabetes-associated renal fibrosis but also attenuates the expression of key pro-inflammatory genes such as tumor necrosis factor-α (TNF-α) and Monocyte Chemotactant Protein-1 (MCP-1). In conclusion, there is a large body of experimental data to support the view that targeting CDA1 is a superior approach to directly targeting TGF-β in DKD since it is not only safe but also efficacious in retarding both fibrosis and inflammation.

Keywords:

diabetic kidney Disease (DKD), diabetic nephropathy (DN), inflammation, fibrosis, TGF-β, SIRT1, CDA1

1. Introduction

It is estimated that diabetes affected 30.3 million people in the USA and 415 million people worldwide in 2018; this number grew to 463 million in 2019 [1] and will increase to 630 million in 2045 [2]. It is believed that approximately half of all patients with type 2 diabetes and one-third of patients with type 1 diabetes will develop diabetic nephropathy (DN) or diabetic kidney disease (DKD) [2]. Despite significant progress having been made in improving glycemic control, DKD remains a major cause of morbidity and mortality in diabetic patients. DKD in some parts of the world represents >50% of patients requiring dialysis and/or transplantation [3]. DKD is clinically diagnosed as the presence of diabetes with impaired renal function and/or elevated urinary albumin excretion, and it is the main cause of end-stage renal disease (ESRD) in both developing and developed countries.

It is well accepted that hyperglycemia and/or its derivative factors alter many cellular signaling pathways, such as the advanced glycation end products (AGEs)/RAGE axis, oxidative stress, Rho-kinase, the diacylglycerol (DAG)-protein kinase C (PKC), polyol, and hexosamine pathways. Increased glucose metabolism results in the excessive production of free radicals, such as reactive oxygen species (ROS). ROS-induced oxidative stress causes DNA damage, specifically strand breakage and base alterations, which activate p53 and its downstream pathways to induce cell cycle arrest or apoptosis [4]. Specific DNA damage in mitochondria results in mitochondrial dysfunction, which in turn generates more ROS. These pathways ultimately lead to a pro-inflammatory response. An increasing number of studies suggest that inflammation, together with oxidative stress and fibrosis, is a key component that plays an important role in the progression of DKD [5]. Fibrosis is the key structural hallmark of DKD, which is commonly observed in association with inflammation. In the last two decades, transforming growth factor-β (TGF-β) has been identified to be a key profibrotic stimulus in the pathogenesis of DKD, and various newly discovered factors have been identified to play significant roles in the inflammatory response. Recently, several molecules involving the TGF-β pathway, such as sirtuin-1 (SIRT1), [6] PTEN, [7] Klotho, [8, 9] BMP7 [10, 11], and cell division autoantigen 1 (CDA1) [12, 13] as well as the functional interactions among some of these molecules, were identified and found to play potential roles in the pathogenesis of DKD, thereby providing novel potential targets to reduce the burden of DKD.

In this review, we summarize the relevant key pathways/cellular events involved in renal inflammation and fibrosis. The two major features of DKD are presented in the Sections “Inflammation in DKD” and “Fibrosis in DKD,” respectively. The interactive relationship between renal inflammation and fibrosis and the molecules/pathways linking both are also discussed.
2. Pathophysiology of DKD

The pathophysiology of DKD is complex. Diabetes causes glomerular hypertension by reducing afferent arteriolar resistance [14]. Hyperglycemia and hypertension gradually lead to glomerular mesangial expansion, which is associated with endothelial dysfunction and further hemodynamic changes. The loss of electric charge and thickening of the glomerular basement membrane, as well as a decreased number of podocytes, impaired podocyte foot process effacement, and mesangial distension, are key features of the initial glomerular injury, which is considered to be critical in the development of diabetes-associated glomerulosclerosis [15].

Alterations in renal tubular function occur in the early stage of diabetes and are often related to the degree of glycemic control. In diabetes, there is a high filtered load of glucose and reabsorption of both glucose and sodium is increased as a result of the upregulation of sodium-glucose cotransporter 2 (SGLT2) in the proximal tubule. These changes ultimately lead to dilatation of afferent arteriole as a result of tubuloglomerular feedback, [16] occurring due to reduced-sodium delivery to the macula densa. Furthermore, interactions among mediators produced by endothelial cells are disrupted. In the endothelium, there is often increased endothelin-1 (ET-1) secretion, arguably the most potent vasoactive peptide, leading to vasoconstriction and vascular dysfunction [16, 17]. In the kidney, activation of endothelin-receptor A mediated by its ligand ET-1 is not only associated with vasoconstriction but also podocyte injury, oxidative stress, inflammation, and fibrosis [18]. On the other hand, hyperglycemia, insulin resistance, and compensatory hyperinsulinemia independently cause endothelial dysfunction by promoting certain intracellular processes. These include the production of ROS, activation of PKC, generation of AGEs, oxidative stress, hypoxia, metabolic and energetic disturbances, overactivation of the renin-angiotensin-aldosterone system (RAAS), and the production of inflammatory and fibrotic factors, including TGF-β [16, 19, 20]. Activation of the intrarenal RAAS aggravates the deterioration of DKD, which has been proven in both animal models and randomized clinical trials [21]. Both TGF-β1 and angiotensin II (Ang II) are involved in the processes that promote renal tissue fibrosis and are also associated with renal tubule dysfunction and atrophy, a reduction in the number of small vessels known as rarefaction, and chronic hypoxia [22]. Aldosterone is also thought to play an important role in the pathophysiology of DKD, through upregulation of pro-sclerotic growth factors, such as plasminogen activator inhibitor 1 (PAI-1) and TGF-β, and promotion of macrophage infiltration and consequent renal fibrosis [23]. Moreover, persistent hyperglycemia leads to endothelial cell apoptosis through the Nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) and c-Jun pathways, resulting in capillary rarefaction, hypoxia, and renal fibrosis [4, 24].

In the early phase of DKD, increased glucose reabsorption, hypertrophy of the proximal tubule cells, increased oxidative stress, and increased TGF-β production are well-documented. These changes lead to downregulation of cell division of proximal tubule cells and promote interstitial inflammation and fibrosis [25, 26]. During DKD, endothelial nitric oxide synthase (eNOS), which is responsible for the production of nitric oxide (NO), is uncoupled. NO, a relaxation factor that dilates the afferent and efferent arterioles, plays an essential role in maintaining kidney function. The lower levels of NO result in lower levels of vessel dilation, rendering the kidney vasculature more sensitive to vasoconstriction mediated by other factors, such as ET-1 [27]. These hemodynamic changes may also predispose DKD patients to acute kidney injury (AKI) [28].

There is an increasing interest in the role of epigenetic pathways in DKD as a potential explanation for the gene/environment interactions that have been linked to this complication [29]. This includes the potential role of DNA methylation and histone modifications in influencing susceptibility and progression of diabetic complications including nephropathy.

The importance of DNA methylation is increasingly being explored [30] although key enzymes mediating this epigenetic process are yet to be shown to be appropriate renoprotective targets. In contrast, certain histone modifications, specifically histone methylation, may be worth to further exploration with seminal studies identifying Set 7 as a histone methyltransferase, which has been shown to play a key role in hyperglycemic memory [31, 32] and has been shown to specifically influence experimental DKD [33]. It is likely that further research in this area will help in explaining susceptibility to DKD, developing new biomarkers to predict and monitor this complication, and finally assist in identifying targets such as enzymes implicated in epigenetic pathways as potential targets for developing renoprotective drugs.

3. Inflammation in DKD

DKD has not been traditionally considered an inflammatory disease. Increasing evidence suggests that DKD is not only solely occurring as a result of uncontrolled hemodynamics and hyperglycemia but also a consequence of a chronically activated innate immune system and a low-grade inflammatory state as seen in patients with diabetes [34, 35]. Furthermore, chronic low-grade inflammation plays a causal role in the progression of obesity and insulin resistance. Thus, inflammation may be a key factor that is activated by the metabolic, biochemical, and hemodynamic derangements known to exist in the diabetic kidney. DKD is associated with both systemic and local renal inflammation with the participation of crucial inflammatory cells, key pro-inflammatory molecules, and various relevant pathways. Among the inflammatory pathways, NF-κB plays a central role through the generation of intricate regulatory circuits that include various cellular mediators, such as adhesion molecules, intracellular second messengers, microRNAs, growth and transcription factors, and cytokines [34]. The infiltration of inflammatory cells and expression of adhesion molecules and cytokines are detected in renal tissues from subjects with DKD. These inflammatory cytokines represent a group of polypeptide signaling molecules that promote autocrine, paracrine, and juxtacrine signaling as part of the innate immune response. Important
markers of inflammation in chronic kidney disease (CKD) are C-reactive protein (CRP), interleukin-6 (IL-6), interleukin-1 (IL-1), tumor necrosis factor-α (TNF-α), adipokines, adhesion molecules, and the CD40 ligand, all of which have been implicated in the progression and severity of CKD. These molecules are produced by various cells including lymphocytes and adipocytes, which become dysfunctional during CKD [36]. Macrophages infiltrate the kidney, and the cycle of cytokine release with further monocyte and macrophage recruitment culminates in inflammation-related structural changes. The magnitude of macrophage infiltration and the extent of mast cell degranulation are associated with the rate of loss of estimated glomerular filtration (eGFR) [37]. Experimental animal models have also provided evidence that some acute phase markers of inflammation, such as intercellular cell adhesion molecule-1 (ICAM-1) and monocyte chemoattractant protein-1 (MCP-1), may have a direct causative role in the development of DKD [34, 38].

3.1 NF-κB

NF-κB, a transcription factor described above, is activated by diverse stimuli, including hyperglycemia, AGEs, mechanical stress, ROS, inflammatory cytokines, Ang II, and albuminuria/proteinuria. In addition, NF-κB plays a central role in the interplay among various factors, molecules, and pathways resulting in structural alterations and functional abnormalities observed in DKD, such as activation of the renin-angiotensin system (RAS), AGEs accumulation, and nicotinamide adenine dinucleotide phosphate hydrogen (NADPH)-dependent oxidative stress [34, 38]. In resident kidney cells, NF-κB is rapidly activated leading to transcription of multiple target genes, including those coding for adhesion molecules, chemokines, inflammatory cytokines, NOS, and other molecules related to inflammation and proliferation, which are all involved in the pathogenesis of DKD [39].

3.2 JAK/STAT Pathway

The JAK (Janus kinase) proteins are intracellular, non-receptor tyrosine kinases that transduce cytokine-mediated signals. Various cytokines act as ligands to bind with cell surface receptors leading to receptor dimerization, which brings the receptor-associated JAKs into close proximity, leading to autophosphorylation of JAKs. The autophosphorylation of the JAK proteins induces a conformational change, allowing the transduction of the intracellular signal by further phosphorylating the receptor dimer leading to the generation of binding sites for SH2 domain-containing proteins, such as STAT (signal transducer and activator of transcription). Upon binding of STAT to the binding site of the receptor, JAKs can phosphorylate and activate the STAT transcription factors. Upon activation, STAT molecules can dissociate from the receptor dimer and translocate to the cell nucleus, where they activate their target genes. JAK/STAT members are controlled in a classical negative-feedback loop by the suppressors of cytokine signaling (SOCS) family (SOCS1–7 and cytokine-inducible Src homology 2 protein (CIS)) [34].

It has been demonstrated that the JAK/STAT pathway plays a role in the pathogenesis of DKD through its participation in several processes, such as the hypertrophy of mesangial cells induced by Ang II and the synthesis of TGF-β, collagen IV, and fibronectin (FN) [34]. Glucose-stimulated production of ROS can activate the JAK/STAT pathway. The upregulation of JAK/STAT has been reported in the glomerular cells of patients with early DKD, and tubulointerstitial expression of various JAK and STAT isoforms increases with disease progression and correlates inversely with the GFR. Although there are several types of JAK proteins, the one primarily studied in renal and vascular tissue is JAK2 [40]. The specific mechanism whereby hyperglycemia promotes JAK2 activation has been related to the interaction between JAK2 and ROS caused by high glucose (HG). ROS enhanced the activity of JAK2, whereas the use of an inhibitor of ROS formation (diphenylene iodonium) resulted in a marked inhibition of Ang II-induced activation of JAK2 [41]. Furthermore, a selective inhibitor of JAK1 and JAK2 was observed in a Phase-2 study to reduce albuminuria in patients with DKD [42].

3.3 Tumor Necrosis Factor-α

TNF-α is a cytokine with prominent pro-inflammatory effects. It is mainly produced by monocytes, macrophages, and T cells, and also by intrinsic kidney cells [43]. TNF-α is produced as a precursor, which is activated by the TNF-α-converting enzyme [44]. There are two TNF-α receptors: the TNF-α receptor 1 (TNFR1) and TNF-α receptor 2 (TNFR2). While TNFR1 modulates the immune response and apoptosis, TNFR2 has been recognized as one of the pro-inflammatory mediators in glomerulonephritis [45, 46]. After binding to these receptors, TNF-α activates an intracellular transduction cascade, leading to the final biological actions of this cytokine, [47] with a potential role suggested in the pathogenesis of DKD. In addition, TNF-α can induce the formation of ROS by renal cells [48]. Experimental researchers have shown that TNF-α induces the activation of NADPH oxidase in isolated rat glomeruli through the activation of the PKC/phosphatidylinositol-3 kinase and MAPK pathways [49]. Thus, TNF-α prompts local ROS production, independent of hemodynamic mechanisms, resulting in alterations of the glomerular capillary wall and consequently increased albumin permeability [50]. In many clinical studies in patients with DKD, the serum and urinary concentrations of TNF-α are found to be elevated as compared with nondiabetic individuals and are highly correlated with the progression of DKD. These findings indicate a potential relationship between the elevated levels of this inflammatory cytokine and the development and progression of renal injury in diabetes [51, 52]. Moreover, serum levels of TNF receptor isoforms are linked to DKD progression [53, 54].

3.4 Monocyte Chemoattractant Protein-1 (MCP-1)

Chemokines play an important role in inflammatory cell recruitment, migration, and interaction, as well as in cellular adhesion, differentiation, and tissue damage in the setting of DKD [55]. Inflammatory chemokines, such as monocyte
chemoattractant protein-1 (MCP-1/chemokine C-C motif ligand 2 (CCL2), C-X3-C motif chemokine (CX3CL1), and CCL5/RANTES (C-C motif ligand 5/regulated on activation, normal T cell expressed and secreted), are upregulated in response to metabolic and hemodynamic factors in the diabetic milieu and participate in the pathogenesis of renal damage in patients with diabetes [56]. Elevated levels of MCP-1/CCL2 have been reported in kidneys and urine from patients with DKD, and they play a role in macrophage infiltration of the glomerulus and tubulointerstitium. Ang II directly induces MCP-1/CCL2 expression, and blockade of the RAS leads to a reduction in MCP-1/CCL2 in the urine. CX3CL1 and CCL5/RANTES are upregulated in diabetes, both within the glomerular and tubular cells and in peritubular capillaries, acting as a chemoattractant for immune cells and cellular adhesion [56]. Indeed, strategies to inhibit MCP-1/CCL2 have been shown to reduce parameters related to inflammation in relevant renal cells and animal models of renal injury, including experimental DKD [57–60]. A small study using an antagonist of MCP-1 receptors CCR2/5 recently showed a modest effect in reducing albuminuria after 12 weeks of treatment in a cohort of type 2 diabetes patients with overt DN [61].

3.5 Adhesion Molecules

The expression of adhesion molecules in DKD is increased in response to TNF-α, NF-κB, and hemodynamic shear stress. Adhesion molecules are upregulated in CKD patients as a consequence of both decreased clearance and increased synthesis [62]. Intercellular adhesion molecule-1 (ICAM-1 or CD 54), vascular cell adhesion molecule-1 (VCAM-1 or CD 106), endothelial cell-selective adhesion molecule (ESAM), and E-selectin are cell surface-localized factors that facilitate intercellular binding, adhesion, and intercellular communication, participating in the pathogenesis of DKD [56]. ICAM-1 exhibits high expression in resident kidney cells, and elevated urinary levels of ICAM-1 are correlated to DKD progression [63, 64]. High circulating levels of soluble forms of VCAM-1 and ICAM-1 are also related to the progression of DKD from microalbuminuria to macroalbuminuria. ESAM reduces glomerular permeability and its downregulation in early DKD may promote albuminuria, whereas soluble levels of E-selectin are positively correlated with albuminuria and cardiovascular disease. VCAM-1 expression is increased in the kidneys of patients with DKD [65] and animal models of DKD [66, 67]. During diabetes, VCAM-1 expression is detected on vascular endothelium and infiltrating cells in the kidney, [66] Increasing plasma levels of soluble VCAM-1 are associated with the progression of albuminuria in patients with type 1 and type 2 diabetes [68, 69].

4. Fibrosis in DKD

Renal fibrosis is often the final common response to injury that leads to the progression of DKD and eventually ESRD. Over more than three decades, a link between mesangial matrix expansion and progression of DKD was demonstrated by a finding that measures of mesangial expansion strongly predicted the clinical manifestations of DKD [70]. Progression of DKD is evidenced by the loss of renal cells and their replacement by extracellular matrix (ECM) in glomeruli and interstitium [71, 72]. Fibrosis is characterized by myofibroblast proliferation and is a condition of excessive accumulation of ECM [73, 74] resulting from the excessive synthesis and decreased breakdown of the ECM, accompanied by an uncontrolled inflammatory response [75].

TGF-β is the primary driver of tissue fibrosis in DKD and indeed in other forms of CKDs [76]. Mechanisms of TGF-β’s profibrotic action in DKD are multifactorial and involve: (1) overexpression of ECM, (2) decreased degradation of ECM, (3) enhanced cross-linking between collagen and elastin fibers, and (4) over-activation of proximal tubular and endothelial cell de-differentiation. Activation of TGF-β leads to activation of myofibroblasts, excessive production of ECM, and inhibition of ECM degradation [76]. ECM primarily contains FN and collagen IV and subsequently serves as a scaffold for the deposition of other proteins, such as collagen type I and type III, which are known as fibrillar collagens [77]. Tubular cell apoptosis and atrophy, lymphocyte and macrophage infiltration, tubular epithelial cell and endothelial cell trans-differentiation, and peritubular vasculature rarefaction are also observed in the fibrotic kidney and could also contribute to the progressive loss of renal function [78, 79]. The reduction in TGF-β bioactivity reduces ECM deposition and attenuates the development of fibrosis in experimental renal injury [80]. Neutralizing all the three mammalian TGF-β isoforms (-β1, -β2, and -β3) with antibodies has been reported to reduce expression of ECM genes (FN and type IV collagen) and attenuates renal fibrosis in mice with type 1 or type 2 diabetes [81, 82]. Thus, TGF-β plays a critical role in ECM accumulation in DKD. Studies on TGF-β inhibition in animal models of kidney diseases have suggested the importance of an anti-TGF-β strategy in ameliorating fibrotic changes [83]. However, direct targeting TGF-β, for example, using a TGF-β neutralizing antibody, appears to be technically difficult and a clinical trial involving such an approach failed to show renoprotection [84].

Connective tissue growth factor (CTGF or CCN2) is a downstream effector induced by TGF-β as part of the fibrosis process. Studies in animal models suggest that CTGF expression in the diabetic kidney is likely to be a key event in the development of glomerulosclerosis by affecting both matrix synthesis and its turnover [85]. A phase I study of a monoclonal antibody against CTGF in humans with diabetes and microalbuminuria demonstrated safety and a small reduction in albuminuria, but larger studies do not appear to have observed significant efficacy [86]. Interestingly, a more recently presented secondary analysis of a large clinical study of patients with type 2 diabetes, the Veterans Affairs Diabetes Trial (VADT) has found that levels of CTGF are associated with and may predict future kidney dysfunction, a finding that may reignite investigation of CTGF inhibition as a potential therapy [87].

Multiple molecules play important roles in preventing the onset and progression of DKD and some of them are demonstrated to be renoprotective. Sirtuins, a family of nicotinamide adenine dinucleotide (NAD)–dependent class III histone deacetylases,
for example, are found to be important regulators in renal protection as they act on many pro-inflammatory and pro-fibrotic factors and regulate their activities. Mammals have seven different sirtuins, SIRT1–7. Each sirtuin plays a different role and has variable expression levels in various tissues and cells with different substrates and their own subcellular distribution. Due to the ability to target post-translational acyl modifications of various cellular substrates, sirtuins are crucial to numerous biological processes including proliferation, DNA repair, mitochondrial energy homeostasis, and antioxidant activity [88].

5. Role of sirtuins in DKD

Caloric restriction not only slows aging and increases lifespan but also increases insulin sensitivity [89, 90]. Dietary restriction in diabetic rat models increased SIRT1 expression in the kidney and improved renal function including albuminuria, creatinine clearance, and renal histology [91, 92]. Thus, caloric restriction activates sirtuins that are beneficial in preventing the progression of DKD. In experimental models of diabetes and some other models of renal injury, renal SIRT1 expression is significantly reduced. Restoration of SIRT1 expression attenuated renal injury in these models and SIRT1 agonists also provided beneficial effects on certain relevant metabolic parameters, such as glucose tolerance, fasting blood glucose levels, and insulin resistance resulting in a prolongation of animal lifespan [93–95].

The loss or injury of podocytes is considered to be a major cause of albuminuria in DKD. Multiple studies have shown that SIRT1 is necessary for the maintenance of cytoskeletal integrity and the survival of podocytes [96, 97]. SIRT1 mediates this process through the deacetylation of cortactin, which plays an important role in the maintenance of the actin cytoskeleton in podocytes [96]. Studies have proven that AGE accumulation downregulates SIRT1 in podocytes, which causes increased acetylation of FoxO4 resulting in apoptosis of podocytes. Moreover, the interplay between SIRT1 and Forkhead Box (Fox) protein O1 (FoxO1) FoxO1 increases the expression of antioxidant enzymes such as Mn-SOD and catalase (CAT) and thereby modulates ROS accumulation [98, 99]. In addition, the SIRT1 agonist, resveratrol, increases SOD activity and reduces malondialdehyde (MDA), collagen IV, and FN expression by increasing FoxO1 activity [100]. SIRT1 deacetylates FoxO3a, which enhances FoxO3a-induced autophagy and exerts antioxidant effects while suppressing FoxO3a-induced cell death. SIRT1 activates autophagy by deacetylating FoxO1 and FoxO3a in the nucleus [101–103]. SIRT1 in tubules downregulates claudin-1 expression in podocytes to protect against diabetes-induced albuminuria [104, 105]. SIRT1 downregulates the expression of claudin-1 by deacetylating histone H3 and H4.

SIRT1 can deacetylate the p65 subunit of NF-κB and inhibit NF-κB’s pro-inflammatory signaling and the downstream production of MCP-1, ICAM-1, and VCAM-1 [106–108]. In the db/db mouse model, deletion of SIRT1 in the podocytes of these diabetic mice results in acetylation of the p65 subunit of NF-κB and STAT3, leading to increased levels of albuminuria [109]. Diabetes-induced downregulation of SIRT1 leading to activation of NF-κB signaling also inhibits the anti-oxidative stress Nrf2/ARE pathway. Podocyte-specific ablation of SIRT1 in db/db mice results in severe proteinuria and kidney injury, which are accompanied by greater acetylation of p65 and STAT3 [109]. NF-κB directly regulates NOX4 expression by binding to its promoter. Downregulation of NF-κB results in reduced NOX4 expression, which ultimately protects against DKD since NOX4 plays a key role in promoting renal oxidative stress and ultimately DKD [110, 111].

Recent research has demonstrated a role for SIRT1 in proximal tubule–podocyte communication in association with the SGLT2. In the diabetic kidney, HG levels within the proximal tubules will trigger glucose transporter 2 (GLUT2)-mediated intracellular glucose uptake via SGLT2 upregulation, causing an associated decrease in SIRT1 [88].

The diabetes-induced decrease in SIRT1 promotes apoptosis in podocytes, ECs, and tubular epithelial cells by the activation of the p53 pathway; and this effect is postulated to cause albuminuria and renal dysfunction in DKD. Acetylation of p53 stabilizes and activates p53 and promotes pro-apoptotic gene transcription, including that of p21 and Bcl-2-associated X protein (Bax). SIRT1 negatively regulates p53 by deacetylating specific residues of p53 [112]. Proximal tubular cells (PTCs) in a HG condition have reduced SIRT1 protein expression, increased expression of c-caspase-3 and c-PARP, and increased acetylation of p53 [113]. In addition, resveratrol treatment restores SIRT1 and prevents increases in expression of p38 and p53. PTC apoptosis, and albuminuria in DKD [113, 114]. A p53/miR-155-5p/SIRT1 pathway has been described in the kidney of animals with DKD, where p53 promotes the expression of miR-155-5p, which reduces SIRT1 expression and promotes p53 activity [115].

The targeted deletion of SIRT1 in proximal tubules of DKD mice results in ectopic expression of the tight junction protein claudin-1 in podocytes, an event that leads to albuminuria and renal functional impairment in streptozotocin (STZ)-induced diabetic mice [104]. These effects were abolished in podocytes exposed to conditional medium from PTCs overexpressing SIRT1, even under HG conditions. These findings reflect the existence of protective factors secreted from SIRT1 overexpressing tubular cells. This functional relationship between proximal tubules and podocytes is referred to as “proximal tubule–podocyte communication.”[104]

Also, SIRT1 modulates angiogenesis through downregulation of vascular endothelial growth factor (VEGF) and Flk-1 (VEGFR-2) expression in HG-treated podocytes and endothelial cells [116].

HIF-1α is a downstream target of SIRT1, and during hypoxia, downregulation of SIRT1 leads to greater acetylation and activation of HIF-1α. SIRT1 deficiency under diabetic conditions leads to activation of HIF-1α, which results in abnormal angiogenesis and fibrosis in the kidney. SIRT1 was also found
to attenuate renal inflammation and fibrosis under hyperglycemic conditions through inhibition of HIF-1α signaling in mesangial cells [117]. Recent studies have demonstrated that hypoxia is also involved in the pathogenesis of DKD [14, 118]. Metabolic changes in diabetic kidneys cause excessive oxygen consumption, resulting in hypoxia and expression of the oxygen sensor HIF-1α. When SIRT1 expression is restored using resveratrol, HIF-1α is deacetylated and inactivated, which prevents the expression of downstream inflammatory factors [118].

AMP-activated protein kinase (AMPK) and SIRT1 have been identified as intracellular energy sensors, detecting and responding to changes in energy depletion and are deactivated in diabetic conditions [119–121]. In hyperglycemic conditions, the downregulation of AMPK/SIRT1/PGC-1α signaling induces hypertrophy, oxidative stress, and mitochondrial and autophagy dysfunction, which all promote the development of DKD. SIRT1 deacetylates lysine residues in liver kinase B1 (LKB1) which catalyzes the phosphorylation and activation of AMPK and downstream signaling [122]. Glucose restriction-induced activation of AMPK increases the activity of SIRT1 by promoting the transcription of the transcription factor TGF-β.

An increasing body of evidence indicates that defective autophagy contributes to the pathogenesis of DKD [124]. Both the AMPK and mTOR pathways regulate autophagy. A decrease in SIRT1 expression inhibits autophagy under diabetic conditions by suppressing the expression of autophagy-related proteins, FOXO and AMPK, and by activating mTOR. Restored SIRT1 increases the expression of FoxO3, which positively regulates BNIP3, and thus enhances autophagy in the kidneys of db/db mice [125]. SIRT1 can attenuate diabetes-related renal fibrogenesis by inhibiting the TGF-β1/smad3 pathway when its expression level is restored. The pro-fibrogenic factor TGF-β1 is upregulated in DKD and activates the downstream mediators Smad2/3 [126, 127]. Phosphorylation and acetylation of Smad2/3 enhance their activity and cause accumulation of ECM [126–128]. However, Smad2/3 have also been identified as targets of SIRT1. Furthermore, resveratrol treatment, to restore the level of SIRT1, deacetylates Smad3 [129].

The associations of sirtuins other than SIRT1 with DKD have also been explored. SIRT3 overexpression suppresses HG-induced apoptosis by reducing ROS accumulation through modulation of Akt/FoxO signaling in PTCs [130]. Furthermore, in mice with DN, the activation of SIRT3 through the G protein-coupled bile acid receptor prevents oxidative stress and lipid accumulation [131]. The restoration of renal SIRT3 protein expression in rats with high-fat-diet-induced DKD has proven to be renoprotective against oxidative stress. On the other hand, SIRT3 suppression is associated with the activation of TGF-β1/Smad3 signaling and increased HIF-1α accumulation, which subsequently causes abnormal glycolysis in PTCs and promotes kidney fibrosis in diabetic mice [132]. SIRT4 overexpression leads to downregulation of apoptosis-related proteins such as NADPH oxidase 1 (NOX1), Bax, and phosphorylated p38, along with upregulation of Bcl-2. These findings are associated with attenuation of the inflammatory response in HG-simulated podocytes [133]. SIRT6 deletion exacerbates podocyte injury in diabetic mice, and SIRT6 overexpression with HG treatment has been reported to protect against podocyte injury through epigenetic regulation of Notch1 and Notch4 transcription due to deacetylation of H3K9 [134]. SIRT6 was also found to regulate the immune response by activating M2 macrophages, which are protective against podocyte injury, in STZ-induced diabetic mice [135]. In a recent study, selective deletion of NAMPT in proximal tubule cells of STZ-induced diabetic mice led to downregulation of SIRT6. This was accompanied by thickening of the tubular basement membrane, type IV collagen deposition, enhanced renal fibrosis, and albuminuria. Selective deletion of SIRT6 in the proximal tubules of diabetic mice caused a phenotype similar to that seen in NAMPT knockout mice. Therefore, the NAMPT–SIRT6 axis in proximal tubules has been suggested to be a key player in the fibrogenic ECM remodeling associated with DN [133].

Because sirtuins maintain important gatekeeping roles in the control of the cell proteome, [136, 137] their function must be tightly controlled. Indeed, each sirtuin is specifically regulated by a rich array of factors in a cell- and tissue-specific manner. Sirtuins are extensively controlled at multiple levels and have been extensively discussed previously [138]. A recent study shows that CDA1 is a negative regulator of SIRT1 [139]. Since CDA1 is a key TGF-β1 enhancer in DKD and a promising target to reduce DKD, the newly known effect of CDA1 on SIRT1 may be able to shed light on the mechanisms whereby CDA1 could be implicated in the pathogenesis of DKD.

6. Actions of CDA1 in DKD

CDA1 was initially identified as an autoantigen reactive with an autoimmune serum from a patient with discoid lupus erythematosus [140]. CDA1 is encoded by the gene Testis-specific Y-encoded-like protein 2 (TSPYL2), which is located on the X-chromosome [141]. CDA1 is also known as cutaneous T-cell lymphoma-associated antigen se20-4, [142] NP79, [143] differentially expressed nucleolar TGF-β1 target (DENTT), which was found to be upregulated by TGF-β1 treatment in lung cancer cells [144]. Later, CASK-interacting nucleosome assembly protein (CINAP) was identified as the mouse homolog of CDA1 [145]. CDA1 acts as an antiproliferative protein via p53/p21, certain cyclins, and cyclin-dependent kinases as well as influencing the ERK/MAPK and TGF-β pathways [54]. In renal and vascular cells, CDA1 has been shown by our group to synergistically enhance TGF-β signaling in human and rodent cells, and indeed, to play a critical pathological role in experimental
Type I receptor (TβRI) expression. Knockdown of CDA1 not only reduces TβRI expression but is also sufficient to inhibit the profibrotic effect of TGF-β, leading to downregulation of sclerotic genes such as CTGF, collagens I, III, IV, and FN [12, 13]. CDA1 gene knockout does not completely block the TGF-β-dependent Smad3 signaling pathway but significantly reduces Smad3 phosphorylation and its transcriptional activity.

Interestingly, diabetic CDA1 knockout mice show an attenuated expression of pro-inflammatory genes, such as TNF-α, MCP1, CRP, ICAM-1, and VCAM-1 accompanied by a marked reduction in ECM accumulation [146]. These findings were further corroborated by studies with a cell-permeable synthetic peptide, which was used to inhibit the activity of CDA1 in diabetic ApoE knockout mice. This led to a marked reduction in not only TGF-β signaling and renal fibrosis in these mice but also pro-inflammatory gene expression [150].

Figure 1. Schematic diagram showing the relationships of CDA1 with profibrotic and anti-inflammatory pathways in the pathogenesis of DKD. CDA1 expression is elevated in DKD. CDA1 enhances the TGF-β/Smad3 signaling pathway by increasing TβRI levels, leading to increased fibrosis. CDA1 can negatively regulate SIRT1, a renoprotective protein deacetylase which is known to be downregulated in DKD, leading to increased inflammation. SIRT1 can deacetylate the p65 subunit of NF-κB leading to inhibition of NF-κB’s pro-inflammatory signaling and the downstream production of pro-inflammatory molecules such as MCP-1, ICAM-1, and VCAM-1. SIRT1 is also known to deacetylate Smad3 leading to inhibition of Smad3-mediated TGF-β signaling and thus reduction of fibrosis. CDA1, cell division autoantigen 1; DKD, diabetic kidney disease; ICAM-1, intercellular adhesion molecule-1; MCP-1, monocytes chemoattractant protein-1; SIRT1, sirtuin-1; Smad3, small mothers against decapentaplegic 3; TβRI, TGF-β type I receptor; TGF-β, transforming growth factor-β; VCAM-1, vascular cell adhesion molecule-1.
A recent study[139] has shown that CDA1 acts as a negative regulator of SIRT1. Furthermore, CDA1-dependent inhibition of SIRT1 leads to increased p53 acetylation as well as intracellular accumulation and increased activity of p53 in the DNA damage response [147]. This finding provides a mechanistic explanation for the observed effect of targeting CDA1 on pro-inflammatory genes in experimental DKD as discussed in Figure 1. SIRT1 is downregulated in DKD, which can, at least partially, occur as a result of an increased level of CDA1. Therefore, it is hypothesized that targeting CDA1 would restore the level of SIRT1, leading to downregulation of various pro-inflammatory genes.

7. Conclusion

In summary, diabetes is a growing pandemic globally with a large number of people affected by the deadly complication, diabetic nephropathy. J Mol Med (Berl) 2019; 97:291–309.
