Secretory tumors of the pituitary gland: a clinical biochemistry perspective

https://doi.org/10.1515/cclm-2018-0552
Received May 26, 2018; accepted July 16, 2018

Abstract: The pituitary gland is responsible for the production and/or secretion of various hormones that play a vital role in regulating endocrine function within the body. Secretory tumors of the anterior pituitary predominantly, pituitary adenomas, collectively account for 10%–25% of central nervous system tumors requiring surgical treatment. The most common secretory tumors are prolactinomas, which can be diagnosed by basal prolactin levels. Acromegaly can be diagnosed by basal insulin growth-like factor 1 levels and the failure of growth hormone (GH) to suppress during an oral glucose tolerance test. Cushing disease can be diagnosed by demonstrating hypercortisolemia evidenced by increased salivary cortisol levels in the evening, increased urine free cortisol excretion and failure of plasma cortisol to suppress following oral dexamethasone given overnight (1.0 mg). We also discuss the diagnosis of the rarer thyroid-stimulating hormone and gonadotrophin secretory tumors. Morbidity is associated with tumor occurrence, clinical sequelae as well as the related medical, surgical and radiological management. This review focuses on the pathogenesis of secretory tumors of the anterior pituitary with emphasis on molecular mechanisms associated with tumorigenesis and the major role of the clinical chemistry laboratory in diagnosis and management of these tumors.

Keywords: acromegaly; adrenocorticotrophin (ACTH); anterior pituitary; clinical chemistry; Cushing disease; growth hormone (GH); prolactin; secretory tumors; thyroid-stimulating hormone (TSH).

List of abbreviation: ACTH, adrenocorticotrophin; ADH, antidiuretic hormone; AIP, aryl hydrocarbon receptor interacting protein; BIPSS, bilateral inferior petrosal sinus sampling; CC, carney complex; CNS, central nervous system; CpG, cytosine linked to guanine nucleotide by a phosphodiester bond; CRH, corticotrophin-releasing hormone; DGSA, densely granulated somatotroph adenomas; EGF, epidermal growth factor; EGFR, epidermal growth factor receptor; FGF-B, fibroblast growth factor-B; FIPA, familial isolated pituitary adenoma; FSH, follicular-stimulating hormone; GH, growth hormone; GHB, GH binding protein; GHR, GH receptor; GHRH, growth hormone-releasing hormone; GnRH, gonadotrophin-releasing hormone; HNF-4 α, hepatocyte nuclear factor 4 α; ICTP, carboxy-terminal cross linked telopeptide type 1 collagen; IGF-1, insulin-like growth factor 1; IPS, inferior petrosal sinus; LDDST, low dose dexamethasone suppression test; LH, luteinizing hormone; MCR2, melanocortin receptor 2; MEN-1 syndrome, multiple endocrine neoplasia type 1 syndrome; miRNAs, micro RNAs; mRNA, messenger RNA; ODST, overnight dexamethasone suppression test; PEG, polyethylene glycol; PKA, protein kinase A; POMC, pro-opiomelanocortin; PRH, prolactin release inhibiting hormone; PRKAR1A, protein kinase, cyclic AMP-dependent regulatory type 1 α; PRL, prolactin; PrRP, prolactin-releasing peptide; PTTG, pituitary tumor transforming gene; SGSA, sparsely granulated somatotroph adenomas; SHBG, sex hormone-binding globulin; T3, tri-iodothyronine; T4, thyroxine; TGF-B, tumor growth factor-B; THR, thyroid hormone resistance; TRH, thyrotropin releasing hormone; TSH, thyroid-stimulating hormone; TSHoma, pituitary adenomas that produce TSH; UFC, urine free cortisol; USP8, ubiquitin carboxyl-terminal hydrolase 8; VEGF, vascular endothelial growth factor; XLAG, X-linked acrogigantism.

Background

The pituitary gland is responsible for the production and or secretion of various hormones that play a vital role in regulating endocrine function within the body.
The pituitary gland consists of two lobes an anterior and a posterior lobe [1]. Hormones produced by the anterior lobe of the pituitary gland include growth hormone (GH), thyroid-stimulating hormone (TSH), luteinizing hormone (LH), follicular stimulating hormone (FSH), adrenocorticotrophin (ACTH) and prolactin (PRL). Hormones stored and released from the posterior pituitary are antidiuretic hormone (ADH)/vasopressin and oxytocin. ADH and oxytocin are produced by neurosecretory cells in the hypothalamus [2]. Trophic hormones produced by the hypothalamus stimulate production of different anterior pituitary hormones which in turn stimulate production of hormones at the level of the target organ [3]. In the case of PRL, secretion is primarily controlled by hypothalamic suppression via dopamine or prolactin release inhibiting hormone [3]. Developmental or acquired pituitary signals may also influence pituitary growth and secretion of hormones [4]. The biology and development of secretory tumors of the pituitary is complex and can cause a variety of endocrine related disorders.

Collectively, the prevalence rate of tumors of the pituitary has been reported to be 16.7%. Other analyses examining post mortem or radiological findings estimate prevalence rates to range between 14.4% and 22.5% [5]. However, many reports reviewing prevalence rates are based on post-mortem and radiological findings and may not provide a true indication of incidences of clinically apparent tumors. One study performed in Argentina described the standardized incidence ratio of clinically relevant pituitary tumors to be 7.39/100,000/year, which was more common than expected by the authors [6]. Another report from a Swedish study described incidence rates for prolactinomas of 1.6/100,000, acromegaly 0.35/100,000, Cushing disease 0.18/100,000, and TSH-producing adenomas of 0.03/100,000 [7].

In this review, we will examine secretory tumors of the anterior pituitary focusing on the pathogenesis of these tumor and the biochemical aspects of diagnosis and management.

**Physiology and biochemistry**

Normal development of the anterior pituitary follows highly specialized precursor stem cell commitment. Somatotrophs account for 50% of pituitary hormone secreting cells, with lactotrophs (10%–25%), gonadotrophs (10%), corticotrophs (10%–20%) and thyrotrophs (10%) accounting for the rest [8].

**Growth hormone**

Somatotrophs are responsible for the secretion of GH, a 191-amino acid single-chain polypeptide [8, 9]. Pit-1/Pou1 F1 and PROP1 are transcription factors that have been reported to play an integral role in the organogenesis of the anterior pituitary and the development of the somatotrophs [10]. The genes responsible for the coding of pituitary human GH, a placental variant and placental lactogen are located on the long arm of chromosome 17. GH exists in various isoforms including 22-kDa form, 20-kDa form, etc. The 22-kDa GH is considered the most relevant isoform in terms of biological activity and constitutes 90% of GH in the circulation [9]. Physiological actions of GH include mediation of skeletal growth and regulation of carbohydrate, fat and mineral metabolism [8, 11]. The growth hormone receptor (GHR) belongs to a family of transmembrane receptors that also includes PRL and cytokine receptors. Biological activity following binding of GH to the cell surface receptor is mediated by dimerization with GHR and activation of JAK2-STAT tyrosine kinase signaling pathway [11, 12]. Many of the peripheral actions of GH are enabled by insulin-like growth factor 1 (IGF-1) which is produced by the liver under the action of GH. Centrally, regulation of GH secretion is controlled by the hypothalamic hormones. Growth hormone-releasing hormone (GHRH) is responsible for stimulating secretion of GH, whereas the hormone somatostatin inhibits GH secretion. Actions of GHRH include inducing GH gene transcription and thus secretion of GH. GHRH is also responsible for maintaining somatotroph cell function. Other hormones that stimulate GH secretion include the gut-derived ghrelin which acts at the levels of hypothalamus to promote GHRH secretion. Somatostatin also plays a role in regulating the timing and amplitude of GH secretion from the anterior pituitary [11].

**Prolactin**

PRL is a polypeptide hormone synthesized by the lactotroph group of cells of the anterior pituitary [9, 13]. Lactotrophs and somatotrophs share the common somatomammotroph lineage thus the presence of GH/PRL pituitary tumors are frequently reported [14]. There are several isoforms/variants of PRL. The major form of PRL in the pituitary is the 23-kDa form; 14-, 16- and 22-kDa forms also exist. Dimerization and binding to larger molecules such as immunoglobulins results in larger isoforms of PRL [15, 16]. Although PRL secretion is regulated by the hypothalamus, unlike other anterior pituitary hormones, the hypothalamic influence is predominantly inhibitory via
the action of dopamine. Stimulation of PRL secretion can be mediated by factors including thyrotropin releasing hormone (TRH) [17]. Other factors that may stimulate PRL secretion include oxytocin, vasoactive intestinal polypeptide, fibroblast growth factor (FGF), endothelial growth factor, hypothalamic prolactin-releasing peptide, galanin, and neurotensin [15, 16]. PRL receptors belong to the same family of receptors as GH and actions are mediated by the JAK-STAT signaling pathway [16]. Physiological function of PRL are mostly related to lactation and reproductive functions [8, 15].

ACTH

ACTH is produced by the corticotroph cells in the anterior pituitary [8, 18]. The primary role of ACTH is related to its stimulatory action on the production and secretion of cortisol by the adrenal glands [19]. It is formed via cleavage of the precursor hormone pro-opiomelanocortin (POMC) by prohormone convertase enzymes [18, 19]. POMC is encoded by a single gene on chromosome 2 [20]. Corticotropin-releasing hormone (CRH) secreted from the hypothalamus positively regulates POMC transcription and thus ACTH secretion. ACTH secretion is pulsatile and demonstrates a typical circadian rhythm. There is negative feedback control from cortisol [18, 19]. Various other hormones and factors influence ACTH secretion, these include inhibitory factors: oxytocin, atrial natriuretic peptide, opiates and stimulatory factors including catecholamines, vasopressin, GH, tumor necrosis factor and interleukins [18]. Both physical and psychological stress play a major role in the secretion of ACTH and cortisol. Other physiological factors such as eating also influence ACTH secretion [21]. The ACTH receptor is located on cells within the adrenal cortex. It is a G-coupled protein receptor known as melanocortin receptor 2. Binding of ACTH to the receptor activates the secondary messenger system resulting in cyclic AMP generation and stimulation of protein kinase-A [15, 18, 19].

Thyroid-stimulating hormone (TSH)

TSH is synthesized within the thyrotrphs of the anterior pituitary. TSH is responsible for the growth of the thyroid and stimulating the production and secretion of thyroid hormones [thyroxine (T4) and tri-iodothyronine (T3)]. TSH – releasing hormone (TRH) secreted by the hypothalamus stimulates the secretion of TSH and negative feedback is regulated by serum T4 and T3 secretions [8]. Like FSH, LH and human chorionic gonadotrophin, TSH is a glycoprotein hormone consisting of an α and β subunit, with the latter conferring biological specificity [8, 15].

FSH and LH

FSH and LH are collectively known as the gonadotrophins and are secreted by the gonadotroph cells of the anterior pituitary [22]. FSH and LH are glycoprotein hormones consisting of α and β subunit [23]. The hypothalamic hormone gonadotrophin-releasing hormone (GnRH) stimulates the secretion of gonadotrophins [8, 24]. The GnRH-gonadotrophin system plays a central role in the regulation of reproduction including steroidogenesis, gametogenesis and ovulation [25]. The actions of GnRH on FSH and LH are not identical. Inhibition occurs from negative feedback from target hormone production, inhibin (FSH inhibition), testosterone and estrogen. However, estrogen is also responsible for positive feedback during part of the menstrual cycle and ovulation [8, 15, 22].

Secretory tumors of the pituitary gland

Pituitary adenomas are the most common cause of hyperpituitarism [8, 26]. These are a diverse group of tumors that are generally benign and slow growing but can also be invasive [1, 8].

Pituitary adenomas are often classified according to size: microadenomas, <10 mm; macroadenomas, ≥10–39 mm; giant adenomas, ≥40 mm. Further classification will depend on histological and immunochemical properties as well as if the adenoma is functional (secretory) or non-functional (non-secretory) [27, 28]. Classification of pituitary secretory tumors may be further performed by immunocytochemical analyses, in situ messenger RNA (mRNA) detection of cell gene products and most commonly and conveniently by measurement of the trophic and target hormone concentrations [1, 8, 28].

Excessive ACTH production leads to hypercortisol-aemia (Cushing syndrome). The incidence of Cushing syndrome is 0.7–2.4 cases per million per year. Pituitary adenomas (Cushing disease) accounts for 75%–80% of ACTH-dependent hypercortisolism and 15%–20% are secondary to ectopic production of ACTH [8, 29–31]. Ectopic CRH producing tumors resulting in Cushing disease are rare and account for <1% of patients with ACTH-dependent Cushing and result in corticotroph hyperplasia [32].
The most common tumors accounting for this increase in ectopic CRH production include medullary thyroid carcinoma, pheochromocytoma and prostate cancer [33]. Cushing disease is more common in females with a ratio of around 8:1 to males and generally presents between 20 and 40 years and is the focus of this review [8, 34].

Excessive production of GH in adults results in the condition known as acromegaly. The tumors are usually macroadenomas and can be sparsely or densely granulated [8]. Sparsely granulated somatotroph adenomas are generally larger, occur more commonly in younger female patients, are more proliferative and have a greater propensity for invasion. Furthermore, densely granulated somatotroph adenomas appear to respond better to somatostatin analogue therapy [35, 36]. Clinical features of acromegaly include skeletal overgrowth of flat bones, for example the mandible; a condition known as prognathism, growth of bones in the feet and hands with resultant increase in shoe and ring size; overgrowth of skin and subcutaneous tissue, increased presence of skin tags; macroglossia; cardiomyopathy; peripheral neuropathy; carpal tunnel syndrome due to compression of median nerve by increased soft tissue growth. Other derangements including features of abnormal glucose tolerance (impaired fasting glucose/impaired glucose tolerance on oral glucose tolerance test) or frank diabetes mellitus as well as hypertension, osteoarthritis and excessive sweating. Additionally, increased serum phosphate levels may be noted [8]. In children, prior to fusion of epiphyseal plates in long bones (e.g. femur, tibia), excessive GH production results in gigantism. Untreated, the condition results in increased morbidity and mortality due to cardiovascular and pulmonary dysfunction [8, 15]. The incidence of acromegaly is 5 cases per million per year and the prevalence is 60 cases per million. Over 95% of patients with acromegaly have a GH-secreting pituitary adenoma derived from the somatotroph cell line. In less than 5% of cases, acromegaly is a result of excessive GHRH secretion from a hypothalamic or neuroendocrine tumor due to somatotroph hyperplasia. Ectopic production of GH is rare [36–38].

PRL hypersecretion leads to gonadal failure, secondary infertility and galactorrhea [8, 15]. Prolactinomas account for around 40% of all pituitary tumors and have been reported to be more common in women [8, 39]. Co-secretion of GH and PRL is relatively common, occurring in 15%–25% of secretory pituitary adenomas [40]. Mixed tumors co-secreting TSH or ACTH may also arise from single cells [1, 8].

TSH-producing adenomas known as thyrotropinomas or TSHomas are very rare and result in hyperthyroidism with a goiter. They represent less than 1% of functioning pituitary adenomas, with the Swedish national registry reporting an incidence rate of 0.15 cases per million inhabitants per year [41]. Gonadotrophin secreting tumors are the rarest and usually present clinically with infertility [8].

Secretoy tumors account for approximately two-thirds of all anterior pituitary tumors [8, 42]. The distribution of functioning adenomas has been reported as follows: GH 14%–30%; PRL 29%–60%; ACTH 13%–25%; gonadotrophins 13%; and TSH 1% [27, 43].

Although the incidence of particular secretory tumors of the pituitary may have a predilection for some populations, as a whole, there are no significant differences in the frequency of pituitary adenomas between the two genders [27, 43]. Additionally, they can be diagnosed at any stage of life but are rarely seen in the prepubertal age group. Small non-functional tumors are generally silent and are discovered as incidentalomas on imaging for investigation for other disorders. Pituitary carcinomas are extremely rare. Primary pituitary hyperplasia is also uncommon [8, 27]. However, pituitary enlargement as a result of lactotroph hyperplasia is a common physiological feature of pregnancy [28, 44]. An approximate twofold increase in pituitary gland size occurs during pregnancy. Nodular hyperplasia, which may involve a single cell type, may mimic a functional adenoma. All cell types may be involved but PRL hyperplasia is the most common, as in pregnancy, resulting in PRL levels of around 200 μg/L [8, 27].

Molecular pathogenesis

The etiology of pituitary tumors are likely multifactorial and involve several initiating and promoting factors. Many of these factors may only be induced after cells have been transformed and are thus not true mechanisms of etiology of the tumors. Benign monoclonal pituitary adenomas arise from a specific cell type [1, 28]. Pituitary microadenomas do not regularly evolve to macroadenomas and both may resolve spontaneously. Development of pituitary carcinoma from adenomas occurs in very rare instances [27, 28]. Additionally, adenoma formation generally does not arise from pituitary cell hyperplasia. This behavior highlights the characteristic of “reversible” plasticity of pituitary adenomas [28]. Mutations resulting in activation of oncogenes such as ras and p53 which are commonly seen in non-endocrine neoplasms have generally not been described in pituitary adenomas [28]. When these are present, they are associated with highly invasive pituitary tumors [28]. The role of the hypothalamus
in pituitary tumorigenesis has been suggested due to the following phenomena: (a) many pituitary adenomas still respond to hypothalamic stimuli, (b) pituitary tumors may resolve spontaneously, (c) success of use of somatostatin and dopamine analogues for tumor shrinkage provides indication of response to hypothalamic stimuli [28, 45–47].

Most pituitary adenomas are sporadic; however, approximately 3%–5% of cases are familial with multiple endocrine neoplasia type 1 (MEN-1) and Carney’s complex accounting for the majority of these [8, 48]. The Carney complex (CC) comprises cardiac myxomas, skin pigmentation and tumors of the anterior pituitary and adrenal gland.

The presence of a pituitary adenoma with pancreatic endocrine tumors and parathyroid tumor constitutes the MEN-1 syndrome. The genetic changes seen in MEN-1 syndrome-related pituitary adenomas is uncommon in sporadic adenomas. MEN-1 syndrome has an autosomal dominant inheritance. The MEN1 gene encodes for a nuclear protein known as MENIN, which plays a role in repressing transactivation as well as regulation of transcription, genome stability and cell proliferation [28, 49]. MEN1 syndrome is linked to the chromosome germine mutation 11q13. Loss of heterozygosity for 11q13 has been reported to occur in 30% of sporadic pituitary tumors. It has been proposed that the MEN1 mutation in these sporadic tumors play a role in progression of the tumor but not initiation [28].

Other genetic syndromes associated with pituitary adenomas include pituitary GH adenomas associated with CC tumors. CC is characterized by microadenomas that arise from GH cells. CC is caused by inactivating mutations or large deletions of the protein kinase, cyclic AMP-dependent regulatory type 1 α (PRKAR1A) gene located at 17q22–24, which codes for the regulatory subunit type 1 α of protein kinase A gene [50, 51].

The McCune-Albright syndrome is another genetic endocrine syndrome associated with pituitary adenomas. The syndrome consists of skeletal and skin defects and pituitary lesions. The genetic defect is the activating gsp mutation in the GNAS1 gene on chromosome 20q13.2. This mutation has also been reported in about 30% of sporadic GH secreting tumors. The gsp mutation is associated with increased transcription of the factor Pit-1 and increased GH synthesis [52–54]. The relatively newly described familial isolated pituitary adenoma (FIPA) is a genetic condition describing pituitary tumors without other endocrine or other associated abnormalities. These account for around 2% of pituitary tumors [55].

Around 20% of FIPA cases have been linked to a germline mutations in the aryl hydrocarbon receptor interacting protein gene and a smaller number are the result of a duplication on the X chromosome in a condition termed X-linked acrogigantism [55, 56]. FIPA may be associated with any of the anterior pituitary gland tumors both secretory and non-functioning with GH-related tumors being the most commonly associated tumor. These patients present in the second or third decade of life and are more likely to have macroadenomas, with more aggressive tumors that are more likely to be treatment resistant [56].

Deletions in the region of 13q14 have been identified in pituitary adenoma. Amplification of HRAS, Cfos and CMYC genes and inactivation of tumor suppressor genes RB1, TP53 and NM23 have been reported to be involved in pituitary tumor progress [28].

The oncogene pituitary tumor transforming gene (PTTG) has been described in wide range of pituitary adenomas [28]. PTTG has been shown to be overexpressed in pituitary tumors and to correlate with tumor invasiveness [57]. Its exact role in tumor pathogenesis is uncertain; however, it has been associated with FGFR to stimulate vascular growth [58]. PTTG has also been identified as belonging to the group of regulatory proteins known as securins which are important in the process of mitosis and regulation of chromosome separation [28].

Other factors described in pituitary tumorigenesis include growth factors such as FGF-B, tumor growth factor-B (TGF-B) and vascular endothelial growth factor. Endocrine trophic factors have also been described as promoting pituitary adenoma formation [59]. Estrogen is mitotic for lactotrophs and gonadotrophs and has been shown to increase TGF-B expression [45]. No mutational events have been unequivocally associated with prolactinomas; however, a significant correlation between estrogen receptor Erα mRNA and PRL level, tumor volume and TGFβ1 mRNA has been observed in prolactinomas. The pathogenetic mechanisms of TSHomas are not well understood. This may in part be due to the rarity of TSHomas (estimated to represent 1%–3% of pituitary adenomas). No mutations have so far been associated with TSHomas [35]. The recently described ubiquitin carboxyl-terminal hydrolase 8 (USP8) gene has been reported to be a somatic mutational hotspot that has been found in up to 50% of corticotrophinomas. Mutations in USP8 lead to a decrease in lysosomal degradation of EGF receptor (EGFR), thereby allowing increased effect of epidermal growth factor due to sustained EGFR cell signaling (an important regulator of corticotroph function) which has increased expression in Cushing disease [38, 60].

The role of epigenetic changes viz. DNA methylation, histone modification and micro RNA (miRNA) have also
been explored. CpG (cytosine linked to guanine nucleotide by a phosphodiester bond) island methylation, which usually encompass the gene promoter regions play a role in regulating transcription. Inappropriate methylation of CpG islands is associated with gene silencing. Suppressed expression of Rb, P16, FGFR2, GADD45γ has been shown in pituitary adenomas, particularly the non-functioning kind [49].

miRNAs are small (~22 nucleotides), non-coding RNA molecules which play important roles in cell proliferation, differentiation, and apoptosis. Certain miRNAs such as miR-128, miR-122 and miR26b have been reported to be associated with secretory tumors of the pituitary [48].

**Diagnosis of secretory tumors**

Clinical suspicion of secretory pituitary tumors mainly arises with the presence of signs and symptoms related to excessive secretion of the trophic and target hormones. Pituitary adenomas may also present because of local mass symptoms, such as headache, increased intracranial pressure, injury of various cranial nerves and visual disturbances. In particular, with regards to the visual disturbances, the compression of the optic chiasm by the pituitary mass may result in characteristic bitemporal hemianopia.

**Clinical biochemistry**

The initial tests should be directed at assaying the hormone whose excess is suspected. Additionally, the possibility of deficiencies of other pituitary hormones should also be considered and relevant testing performed as detailed previously [8, 61]. Patterns of excessive secretion of hormones are not uniform and may cycle between normal and excessive secretion due to the pulsatile nature of their secretion.

**Excessive production of growth hormone**

**Growth hormone measurement**

Random GH levels are usually not recommended due to the diurnal and pulsatile nature of secretion that occurs during a day [11]. However, although a randomly elevated GH level does not imply presence of excessive secretion, it has been reported that random values of less than 0.04 ng/L can be utilized to exclude the diagnosis of acromegaly [37]. Dynamic function (suppression) testing forms the cornerstone of laboratory investigations of GH excess.

Oral glucose tolerance test: A hallmark of a GH secretory pituitary tumor is the inability to respond appropriately to a glucose-induced suppressive signal. The oral glucose suppression test involves intake of 75 g of glucose with measurement of GH levels at 0 and 120 min. A GH level at 120 min of <1 μg/L usually excludes the diagnosis of acromegaly [36]. However, this cut-off has been reported as being less sensitive, with recommendations of lower levels cut-offs (<0.3 μg/L) with more sensitive assays [37]. Rarely, there is a paradoxical increase in GH levels during the OGTT. The GH level following OGTT can be impaired by aging, female gender and obesity [36].
of the pituitary extracts was unknown and an arbitrarily chosen value was assigned. Newer standard materials IS 88/624 and more recently IS 98/574 (current in use standard preparation) used recombinant GH [62]. Recommendations from a joint meeting in 2010 held with the Growth Hormone Research Society in collaboration with the International Federation for Clinical Chemistry and Laboratory Medicine, the International Society for IGF Research and the Pituitary Society were that for GH assays apart from adoption of one defined IS, the isoform specificity of assay antibodies should be known and should ideally only recognize the 22-kDa isoform [65].

The other issue with use of GH assays is the interconversion between SI and conventional units. This has significant impact on clinical decision limits which to date have been used with little regard for assays used for the GH determination and assay of origin for the cut-point. Current recommendations for GH assay performance is that the assay achieve a lower limit of quantification of 0.05 μg/L with a CV of <20% [65].

**IGF-1 measurement**

IGF-1 is reflective of integrated cumulative exposure of peripheral tissue to excessive GH concentrations and, as a mediator of GH is elevated in the presence of increased GH levels. It has been recommended as the initial screening test for GH excess for the following reasons: (a) unlike GH which requires suppression testing and fasting samples, random samples can be used for IGF-1 measurement; (b) IGF-1 is not subject to diurnal, pulsatile variation as with GH and is not influenced by other pre-analytical factors such as recent meal ingestion, exercise and sleep and has a longer half-life due to its binding proteins [8, 37, 66]. However, there is significant within person biological variation (3%–36%) reported for IGF-1 [67]. Other factors including aging, pubertal development, extremes in body mass index, pregnancy, uncontrolled diabetes, malnutrition, hypothyroidism, hepatic and renal diseases affect IGF-1 levels [36]. Since IGF-1 is age and gender dependent (particularly in children and adolescents) it is vital that the appropriate age and gender related reference intervals be utilized when interpreting results. Additionally, reference intervals defined need to be method/assay specific. The mainstay of IGF-1 measurement remains immunoassay platforms. Standardization of IGF-1 remains an issue with poor agreement between different immunoassays [67]. Krebs et al. reported regression slopes of between 0.527 and 1 when five different immunoassays were compared to the former gold standard, the Nichols Advantage assay. Currently, a reference standard IS 02/254 using recombinant material is available [68].

Like GH, IGF-1 also has binding proteins which may affect assays by interfering with antibody binding sites generally resulting in falsely low results. Different methods of removal of the binding proteins also leads to poor between-assay correlations [65]. Recently reports have described the use of LC-MS/MS methods for the determination of IGF-1 [69, 70]. Being a small molecule IGF-1 lends itself to better performance in terms of specificity and accuracy using this methodology. An enrichment step is usually carried out before sample extraction, which would require a step for disassociation of binding proteins from IGF-1 [70].

It is interesting to note that several strides in GH and IGF-1 measurement have been made because of their use as performance enhancing agents and the efforts of anti-doping agencies to detect their illicit use.

About 15% of patients with acromegaly can have a tumor producing both GH and PRL [8]. Although our focus is on the clinical biochemistry, it is important to emphasize that imaging with magnetic resonance imaging (MRI) is crucial in the diagnosis since the majority of tumors are macroadenomas and can be invasive [8, 42]. It is prudent to undertake a colonoscopy to rule out the increased risk of colonic neoplasms and sleep studies to rule out obstructive sleep apnoea. Early diagnosis and management of acromegaly is of great importance given the twofold increased mortality largely from cardiovascular causes [42]. Biochemical goals of therapy include IGF-1 levels in the age appropriate reference range and a random GH level <1 μg/L [42].

**Prolactinoma**

Prolactinomas represent at least 50% of all secretory adenomas of the pituitary and present with galactorrhoea and amenorrhea in women and decreased impotence and libido in men (hypogonadism in both men and women) [8, 71]. PRL levels should be assayed in patients with hypogonadotrophic hypogonadism and males with hypogonadism and infertility. Basal levels of PRL are useful with values of >100 μg/L generally associated with the presence of a prolactinoma usually a microadenoma and >200 μg/L due to a macroadenoma. PRL levels generally parallel the tumor size. PRL may be increased due to other causes non-related to presence of a pituitary secreting...
tumor. These include pituitary stalk disease and various medications that inhibit dopamine. Since drug ingestion is a very common cause of elevated PRL levels, a careful history needs to be taken to exclude estrogen therapy, dopamine antagonists (such as metoclopramide, opioids and phenothiazines) and use of monoamine oxidase inhibitors [8]. Physiological conditions such as pregnancy and pathological conditions such as primary hypothyroidism, cirrhosis and chronic kidney disease also result in elevated PRL levels [8, 72]. In most of the above conditions PRL levels rarely exceed 100 μg/L.

PRL is routinely measured by immunoassay methods commonly using chemiluminescence or electrochemiluminescence methods. The presence of macroprolactin, a biologically inactive but immunoreactive form of PRL that is bound to immunoglobulin G, results in falsely elevated PRL levels to differing extents in currently available commercial assays. The vast majority of patients with macroprolactinemia are asymptomatic; however, some may have few nonspecific symptoms that may also occur in hyperprolactinemia, thus confounding the clinical differentiation of those with true monomeric increase from those with macroprolactin [73–75]. It is a rare occurrence but laboratorians need to be aware on how to exclude macroprolactinemia. The structure of macroprolactin and its interaction with the different assays are variable [76].

In suspected macroprolactinemia, laboratory procedures for confirming macroprolactin are recommended [77]. It is important that whichever method is used for the detection of macroprolactin, it has been validated for use with the assay platform used to measure PRL. The simplest of these involve precipitation of the macroprolactin component following treatment of the patient sample with a polyethylene glycol solution and then measurement of the PRL in the supernatant of the treated sample [78]. Partial precipitation of certain immunoglobulin groups may occur together with interference in some manufacturer assays [79]. Gel filtration chromatography is the gold standard for measurement of monomeric PRL but is costly, technically demanding and may cause an under- or overestimation due to denaturation of adsorption during the gel run [80–87]. Other methods for detection of macroprolactin include ultrafiltration and immune-adsorption, which are also not commonly performed in routine laboratories [82].

An additional issue related to the laboratory measurement of PRL using immunoassay based platforms is the presence of the hook effect. The hook effect results in falsely low or normal results in the presence of true high values of PRL due to the prozone phenomenon [83]. This can be easily overcome by dilution of the specimen 1/20 or 1/50. The hook effect is usually suspected with larger tumors and the clinical syndrome without a commensurate increase in PRL.

**Cushing disease: endogenous ACTH excess**

The laboratory investigation of Cushing disease begins with the confirmation of excessive endogenous corticosteroid production followed by identification of ACTH-dependent production and determination of site of ACTH production [84, 85]. An absolute requirement prior to biochemical investigation is to exclude exogenous intake of glucocorticoids [85].

**Tests for confirmation of hypercortisolemia**

Confirmation of hypercortisolemia often remains a diagnostic challenge with more than one test for hypercortisolemia usually being required.

(a) Serum or salivary samples may be used to obtain a midnight cortisol level. Cushing syndrome is associated with a loss of circadian rhythm of cortisol production and there is an accompanying loss of the normal nadir of cortisol at midnight. Serum cortisol greater than (5 μg/dL) or salivary cortisol greater than (0.15 μg/dL) is in keeping with a diagnosis of Cushing syndrome [84, 85]. Sensitivity and specificity (92%–100% each) of midnight salivary cortisol levels have reported superiority to other screening methods for hypercortisolemia [84]. Utility of salivary cortisol is more convenient for patients as collection may be done at home. Collection is done using devices such as Salivette collection device. Patients need to be instructed appropriately regarding collection of saliva in particular avoiding collection in the presence of mouth ulcers, etc. and avoidance of aggressive tooth brushing prior to collection as contamination with blood will result in a falsely elevated salivary cortisol. Salivary cortisol increases with aging, diabetes and hypertension [85]. However, it appears to be superior to 24-h urine free cortisol (UFC) in confirming a diagnosis of Cushing syndrome. At least two collections should be performed to confirm positive results [85].

(b) 24-h UFC measures unbound (free) cortisol excreted in the urine.
The assays of choice are either HPLC or tandem MS. Immunoassays are very unreliable due to cross-reactivity from other metabolites. The unbound fraction is the active fraction in serum and comprises 2%–3% of the total circulating cortisol [19]. The upper limit of normal for the particular assay used is recommended as the criterion for a positive test, provided the creatinine shows that the collection is complete and the volume is not excessive. Generally, 24-h UFC values above two to three times the upper limit of normal are suggestive of hypercortisolemia. It cannot be used in patients with significant renal impairment and has low sensitivity and specificity. False-positive results may be seen with high fluid intake and urine output >5.0 L/24 h, depression and excessive alcohol intake [84]. When HPLC is used, both fenofibrate and carbamazepine can co-elute resulting in false positives [19]. False negatives can result with chronic kidney disease with a decrease in e-GFR [85]. At least two collections should be performed to confirm findings [85].

(c) Overnight dexamethasone suppression test (ODST): 1 mg of dexamethasone is administered between 11 pm and midnight and the serum cortisol is measured the next morning between 8 and 9 am. In normal individuals the cortisol is suppressed below 1.8 μg/dL. A morning cortisol value of less than 5 μg/dL has also been previously described as a cut off for adequate suppression. However, current guidelines recommend the 1.8-μg/dL cutpoint as the higher value of 5 μg/dL led to misclassification of up to 15% of patients with Cushing syndrome as negative [84–86]. Drugs affecting the absorption and metabolism of dexamethasone such as phenytoin and carbamazepine may affect results resulting in false positives.

False positives for the ODST may also occur with obesity, depression, chronic alcoholism and high estrogen states [84]. Failure of patients to take the dexamethasone dose would also result in false positives. Additionally, the wide inter-personal variation in dexamethasone metabolism as well as the effect of a number of commonly used medications on the metabolizing CYP3A4 enzyme complex may result in false positive or negative results [85]. Measurement of serum dexamethasone in any suppression test is useful to assess if adequate levels of drug are present for a valid result [87].

(d) Low dose dexamethasone suppression test (LDDST): In this test, 0.5 mg of dexamethasone is taken orally every 6 h for 48 h. The initial dose on day 0 is taken at 9 am. The serum cortisol is measured between 8 and 9 am at 24 and 48 h respectively after the start of the test [19]. The same cortisol decision level for ODST is used [84]. The ODST has largely supplanted this test which is far more cumbersome.

(e) In patients with cyclical Cushing or where there is strong clinical suspicion of disease but tests for hypercortisolemia have been negative – the dexamethasone – CRH test has been used. This is based on the theory that a small number of patients with Cushing disease as well as normal individuals will show suppression to dexamethasone, but those with Cushing disease will respond to CRH with a rise in ACTH and cortisol [88]. The procedure for this test involves individuals receiving 0.5 mg dexamethasone orally every 6 h for eight doses. Blood samples for serum cortisol are taken 2 h after the last dose of dexamethasone and just before administration of intravenous bolus injection of 100 μg CRH. Serum samples for cortisol are taken at 15, 30, 45, and 60 min after CRH. A serum cortisol concentration of 1.8 μg/dL or less after the LDDST and of <1.4 μg/dL or less 15 min after CRH injection is considered normal [89].

**Determination of ACTH dependence/independence**

(a) Measurement of ACTH: Increased ACTH levels in the presence of elevated cortisol secretion supports the presence of an ACTH-dependent cause of Cushing syndrome. If ACTH is >15 pg/mL, it is an ACTH-dependent cause of Cushing syndrome. It has also been noted that patients with ectopic ACTH and CRH secretion usually have higher levels of ACTH than those with Cushing disease [88].

(b) High dose dexamethasone suppression test: This is based on the principle that most pituitary corticotroph tumors do retain some degree of responsiveness to negative glucocorticoid feedback, whereas ectopic ACTH-secreting tumors typically do not. Two milligrams of dexamethasone is administered every 6 h for 48 h or with a single dose of 8 mg. Eighty percent of patients with Cushing disease will suppress their plasma cortisol to below 50% of baseline plasma cortisol levels [88].

(c) CRH stimulation test: CRH is produced by the hypothalamus and stimulates production of ACTH by the pituitary [18, 19]. In this test CRH is administered intravenously and ACTH and cortisol are measured at baseline and at 15, 30 and 45 min thereafter. A rise in ACTH greater than 40% and cortisol levels greater
than 20% indicate an ACTH-dependent cause most likely Cushing disease, as ectopic sources of ACTH are not usually responsive to CRH stimulation [19].

The CRH stimulation test may be accompanied with bilateral inferior petrosal sinus (IPS) sampling to confirm the presence of a pituitary lesion causing Cushing. During this invasive procedure the IPSS into which the pituitary venous blood drains is catheterized by a radiologist. ACTH is measured at baseline and following stimulation with 100 μg of CRH from both IPS and peripheral veins. Measurement of PRL is also performed to confirm the catheter is in the correct position. A ratio of IPS to peripheral ACTH of 2:1 before CRH stimulation and 3:1 after stimulation indicates a pituitary cause of ACTH-dependent Cushing syndrome [88, 90]. False negative results with BIPSS include cyclic or mild Cushing syndrome, tumor with low responsiveness to CRH, ectopic tumor located in sphenoid sinus, false positives are less common. Technique with regards to catheterization and anatomical variants with regards to pituitary venous drainage may also affect performance of test and the testing should be undertaken in centers with expertise in this area [90]. BIPSS sampling is the most definite test in our repertoire to confirm pituitary dependent Cushing disease with a sensitivity and specificity of around 95% [91].

**Assay issues**

Women receiving oral estrogen therapy may have elevated levels of cortisol-binding globulin resulting in high total serum cortisol levels; however, UFC and salivary cortisol which are unbound are not similarly affected [42]. Measurement of salivary cortisol may be performed by adaptation of commercial serum immunoassays or LC-MS/MS methodologies. Analytical sensitivity and specificity of around 95% [91].

**TSH-producing adenoma**

Thyrotropinomas or TSHomas are characterized by a pituitary tumor coupled with increased TSH, T4 and T3 levels [85]. Since glycoprotein hormones have α and β subunits, tumors can produce an excess of the α subunit of TSH in thyrotropinomas and an abnormally high α subunit (ng/mL) to TSH (mIU/L) molar ratio (>1) will be seen. Other measures of hyperthyroidism that can be useful include elevated levels of sex hormone-binding globulin (SHBG) [94]. Increase in SHBG levels is thought to be an indirect effect of increase thyroid hormones in circulation causing an increase in hepatocyte nuclear factor 4 α levels in hepatocytes which in turn promotes SHBG formation [95].

Patients with TSHomas also have elevated levels of serum carboxy-terminal cross linked telopeptide type 1 collagen (ICTP). This is indicative of the hypermetabolic state of bone in hyperthyroidism.

TRH stimulation test can be used to evaluate patients with suspected TSHomas. Following administration of TRH, TSH is measured. There is a lack of a normal TSH response to TRH in TSHoma [94]. The T3 suppression test has also been used to detect the presence of a TSHoma. After T3 suppression test (80–100 μg/day for 8–10 days) the inhibition of TSH seen in normal individuals will not be observed with TSHoma. However, this test should not be done if there is concomitant cardiovascular or pulmonary diseases [96]. Most TSHomas retain responsiveness to somatostatin and T4 and T3 levels fall following administration. This can also be used to assess if somatostatin analogues will be an effective treatment [97].

In the presence of elevated TSH and normal/high thyroid hormone levels it is important to exclude a potential analytical interference, poor compliance in a patient with known hypothyroidism and thyroid hormone resistance...
The presence of a pituitary adenoma on imaging, together with features of concomitant hypersecretion of other anterior pituitary hormones will aid in confirming the diagnosis TSHoma. Patients with THR often have a family history of this disorder and lack the elevated α subunit, SHBG and ICTP levels found in TSHomas. Familial TSHoma is rare. Additionally findings on TRH stimulation are normal or exaggerated TSH responses and suppression of TSH with T3 with THR [98]. Patients with THR have normal ICTP levels. Administration of somatostatin reduces serum TSH levels in TSHoma but not in THR [96–98]. Since the differentiation of THR from TSHoma can be challenging, all of the above tests can prove helpful.

### Gonadotrophin secreting adenomas

These tumors are usually macroadenomas and can cause visual impairment. Usually, the patients have hypogonadism with elevated FSH and α subunit levels and MRI confirms the tumor [8].

### Imaging studies

Pituitary imaging studies using unenhanced or contrast enhanced MRI are preferred to computed tomography scans for visualization of pituitary adenomas [42, 99]. Often pituitary adenomas are discovered incidentally when imaging studies have been done for other reasons. Formal visual fields need to undertaken when there is a

macroadenoma given the proximity of the optic chiasma to the tumor. Diagnostic tests utilized in the diagnosis of anterior pituitary secretory tumors are summarized in Table 1.

Management

Management of hyperpituitarism will depend on the cause and the hormone/s effected. For both acromegaly and Cushing disease surgical removal of the adenoma is the treatment of choice. Pharmacological treatment includes the use of somatostatin analogs (e.g. octreotide, lanreotide) can be effective adjunctive for acromegaly, Cushing and TSHoma. Also, competitive GHR antagonists can be useful in acromegaly. For prolactinoma, medical treatment with dopamine agonists is the preferred choice [42].

Surgical management: Apart from prolactinoma, for most pituitary tumors, surgery is the first-line treatment [42]. Resection of pituitary tumors is technically challenging because of the anatomical location. Minimally invasive procedures (trans-sphenoidal surgery) are being increasingly utilized.

Conventional radiotherapy may be used to reduce tumor size; however, pituitary damage and resultant hypopituitarism may result. Stereotactic radiotherapy has been associated with fewer adverse effects that conventional radiotherapy although the risk of hypopituitarism is similar for both [99]. Irradiation is the adjunct therapy used for patients who do not achieve adequate reduction in tumor size, hormone levels, or both in response to surgery, medical therapy, or both [42].

Conclusions

In this review, we have updated and summarized the physiology and biochemistry of pituitary hormones and the pathogenesis of the secretory tumors. However, our major focus was to update laboratorians especially PhD clinical chemists and trainees on how to confirm the diagnosis of the different secretory tumors.
