Summary
Moyamoya disease is the chronic cerebrovascular disease, which is characterized by progressive occlusion of the intracranial part of internal carotid arteries and their proximal branches. Revascularization surgery of the ischemic hemisphere is a frequently recommended kind of treatment Moyamoya disease patients and it allows to prevent against stroke and to improve blood perfusion of the brain. We present the one case with treatment of this disease using superficial temporal artery (STA) – middle cerebral artery (MCA) bypass.

Key words: Moyamoya disease, STA-MCA bypass

AIM OF THE DEMONSTRATION
The aim of this demonstration is to report about our experience in treatment of rare in our region patient with Moyamoya disease.

CASE REPORT
55-year old woman was presented with history of ischemic strokes in the left anterior cerebral artery perfusion area 4 years ago and in the right middle cerebral artery perfusion area 2 years ago. Headaches, vomiting, dizziness, seizures, transient ischemic attacks, which are characterized as weakness or sensory loss during few minutes, speech difficulty, darkening of vision during few seconds, were presented in a current of 5 years and these neurological symptoms became more frequent and worse.
Preoperative MRI examination of the brain showed the old cerebral infarcts in the left frontal and right parietotemporal region.

Preoperative A right and left carotid angiograms (Fig.1) were performed with diffuse stenosis of both side internal carotid arteries and the classical “puff of smoke” appearance was seen in the right and left cerebral circulation (Fig.2).

Fig. 1 - Angiogram A, lateral projection, shows abnormal collateral vessels network (white arrows) and the angiogram B shows diffuse stenosis of the internal carotid artery (black arrow) with occlusion of ophthalma segment (white arrow).

The first operation was done on the right hemisphere on 5th of January 2011 and the second – on the left hemisphere on 2nd of May 2011. In this surgical procedures were performed both side STA-MCA bypass, where STA was used as a donor artery and MCA as a recipient artery.
Few days after each operation patient felt much better and noted that arms and legs became agile and more powerful. During the year coming to examinations and controls patient had not complained of symptoms, which were presented before, except headaches.
Postoperative angiograms were performed, that, during the year, anastomoses work on both sides and were noticeably reduced quantity of Moyamoya vessels (Fig.3).
DISCUSSION

The etiology of Moyamoya disease is unknown, but the pathological analysis had revealed, that this disease is characterized by the intimal thickening and attenuation of tunica media of the proximal vessels of the circle of Willis as well as the development of small collateral net-like vessels. The primary proteins that are currently implicated in the pathophysiology of Moyamoya disease include vascular endothelial growth factor, basic fibroblast growth factor, hepatocyte growth factor, transforming growth factor-β, and granulocyte colony-stimulating factor. Also the current literature has pointed to a low penetrance autosomal dominant or polygenic mode of transmittance at loci on chromosomes 3, 6, 8, 12, and 17 (13), as well as specific alleles of class II genes of the human leukocyte antigen have been described. (5) Nowadays therapy is aimed on preventive actions against a stroke and to improve circulation of the brain, as well as multiple burr holes procedure, in which several small holes are placed in the skull. Over time the result of angiogenesis is the formation of small arterial vessels, which germinate into the brain and increase the blood perfusion. (7) (8) (9) (10) There are possible negative effects of this method: necessary time for neovascularization, that means, that we cannot evaluate effect in short time after surgery, because of new vessels need at least few months to germinate into the brain and there is a possibility that process of angiogenesis could be not enough to provide normal perfusion of the brain. (3)

We decided to use STA-MCA bypass in treatment of our Moyamoya patient, because this is the most studied method of management Moyamoya disease, and this method allow immediately realise our main aim - increase blood flow in ischemic hemisphere. Also there is a possibility to use a combination of both revascularization methods with good short-term and long-term outcomes. This treatment could be used as a first step in Moyamoya disease treatment or after unsuccessful indirect surgery, when neovascularization process cannot provide necessary blood perfusion. (1) (4) (6) (11)
