Abstract

**Introduction:** The toxinotyping and antimicrobial susceptibility of *Clostridium perfringens* strains isolated from processed chicken meat were determined. **Material and Methods:** Two hundred processed chicken meat samples from luncheon meats, nuggets, burgers, and sausages were screened for *Clostridium perfringens* by multiplex PCR assay for the presence of alpha (*cpa*), beta (*cpb*), epsilon (*etx*), iota (*iia*), and enterotoxin (*cpe*) genes. The *C. perfringens* isolates were examined *in vitro* against eight antibiotics (streptomycin, amoxicillin, ampicillin, ciprofloxacin, lincomycin, cefotaxime, rifampicin, and trimethoprim-sulfamethoxazole) **Results:** An overall of 32 *C. perfringens* strains (16%) were isolated from 200 processed chicken meat samples tested. The prevalence of *C. perfringens* was significantly dependent on the type of toxin genes detected (*P = 0.0*), being the highest in sausages (32%), followed by luncheon meats (24%), burgers (6%), and nuggets (2%). *C. perfringens* type A was the most frequently present toxinotype (24/32; 75%), followed by type D (21.9 %) and type E (3.1%). Of the 32 *C. perfringens* strains tested, only 9 (28%) were enterotoxin gene carriers, with most representing type A (n = 6). *C. perfringens* strains differed in their resistance/susceptibility to commonly used antibiotics. Most of the strains tested were sensitive to ampicillin (97%) and amoxicillin (94%), with 100% of the strains being resistant to streptomycin and lincomycin. It is noteworthy that the nine isolates with enterotoxigenic potential had a higher resistance than the non-enterotoxigenic ones. **Conclusion:** The considerably high *C. perfringens* isolation rates from processed chicken meat samples and resistance to some of the commonly used antibiotics indicate a potential public health risk. Recent information about the isolation of enterotoxigenic *C. perfringens* type E from chicken sausage has been reported.

**Keywords:** processed chicken meat, *Clostridium perfringens*, enterotoxin, antimicrobial resistance.

Introduction

The microbiological quality and safety of meat are significant for the health of consumers around the world (25). Anaerobic bacteria constitute an important group of microorganisms that are responsible for many public health hazards. *C. perfringens* is a member of this group that is more widely spread than others, since its principal habitats are the soil and intestinal contents of humans and animals (18). Disease flare-up due to *C. perfringens* can have various origins, one of which is poultry (15).

In poultry, *C. perfringens* constitutes a human health hazard through the food chain and is one of the most frequently isolated bacterial pathogens from chicken meat, constituting up to 70%–98% of the cases (7, 9). *C. perfringens* is an omnipresent pathogen of the intestinal tract of poultry, associated with different phases of poultry growth and production. Chicken carcasses and meat parts may likewise be contaminated with *C. perfringens* during evisceration in the slaughterhouse (29).

*C. perfringens* causes a number of human diseases ranging from necrotic enteritis to wound infection and life-threatening gas gangrene (21). *C. perfringens* has been grouped into five types (A-E) based on toxins produced (*alpha, beta, epsilon, and iota*). The *alpha* toxin is produced by all the types of *Clostridium perfringens*. The toxin is a necrotising toxin which is believed to be a virulence marker (4, 22). In addition, *C. perfringens* produces other minor toxins, such as enterotoxins, which are not associated with a specific strain and are responsible for causing the gastrointestinal disorders that may be food- or non-food-borne.
The enterotoxin gene (cpe) exists on either a chromosome in food-poisoning isolates or a large conjugative plasmid in non-food-borne gastrointestinal disease (12).

Our study aimed to detect the presence of *C. perfringens* in processed chicken meat samples (luncheon, nuggets, burger, and sausage) and characterise the isolates for the existence of enterotoxin gene. In addition, the *in vitro* resistance of *C. perfringens* isolates against certain antibiotics was determined.

**Material and Methods**

**Samples.** In total, 200 processed chicken meat samples of luncheon, nuggets, burger, and sausage (n = 50 each) were collected from different markets in Cairo during the period from March to April 2015. When collected, the samples were directly transferred in iceboxes to the laboratory.

*C. perfringens* isolation and identification. Ten grams of each sample was diluted in 90 mL of sterile 0.1% peptone water and homogenised in a blender at 2000 rpm for 1–2 min. About 1 mL of each homogenised food suspension was inoculated into cooked meat broth tubes and incubated anaerobically at 37°C for 48 h. A loopful form each tube was streaked on neomycin sulphate sheep blood agar plates and incubated anaerobically for a further 48 h. Suspected colonies were examined microscopically and biochemically (9).

DNA extraction and PCR assay. DNA was extracted from pure colonies of *C. perfringens* that showed a double zone of haemolysis on blood agar by using an extraction kit (QIA amp Mini Kit, Qiagen, Germany). Specific oligonucleotide primers for the alpha (cpa), beta (cph), epsilon (etx), and enterotoxin toxin (cpe) genes of *C. perfringens* were used as described in Table 1. Multiplex PCR assay was carried out in a reaction mixture (25 µL) containing 1 µL of template DNA, 12.5 µL of Dream Taq Green PCR Master mix, 0.5 µL of each primer (10 pmol/µL), and 10.5 µL of DNase-free water. PCR amplification was carried out in a Biometra PCR thermal cycler. Following initial denaturation for 3 min at 94°C, the samples were subjected to 35 cycles of denaturation at 94°C for 1 min, annealing at 55°C for 1 min, extension at 72°C for 1 min, and final extension for 10 min at 72°C (28). The PCR reaction mixtures were analysed by electrophoresis using 1.5% (w/v) agarose gel in the presence of 100 bp DNA ladder (Fermentas Life Science, EU) (14). Types D and E, and positive-control of national *C. perfringens* strains were also included in the PCR.

**Antimicrobial sensitivity test.** Thirty-two *C. perfringens* isolates were examined *in vitro* against eight antibiotics, which included streptomycin (10 µg), amoxicillin (10 µg), ampicillin (10 µg), cefotaxime (30 µg), ceftriaxone (30 µg), rifampicin (5 µg), and trimethoprim-sulphamethoxazole (1.25 + 23.75 µg) (Oxoid, UK). The test was carried out using the agar disc diffusion test, (17, 26). The isolates were cultured anaerobically at 37° for 24 h in 10% neomycin sheep blood agar, then suspended in 0.9% NaCl to a 0.5 McFarland standard. Every isolate was inoculated onto Mueller-Hinton agar plates (Remel, USA) and the antibiotic discs were applied. The plates were incubated anaerobically at 37° for 24 h. The interpretation of the results was performed according to CLSI, 2012 (8).

**Statistical analysis.** PASW Statistics. Version 18.0. software (SPSS Inc., USA) was used to analyse the data. The Chi square (x²) test was applied (provided that at least 80% of the cells had an expected frequency of five or greater, and that no cell had an expected frequency smaller than 1.0). Otherwise, the Fisher-Freeman-Halton Exact test was used (i.e. the Fisher’s Exact test for contingency tables larger than 2x2). A value of P < 5 was considered as significant.

**Results**

Overall, 32 *C. perfringens* isolates were obtained from 200 processed chicken meat samples (luncheon, nuggets, burger, and sausage; 50 of each with an incidence of 16%, Table 2). There was a relationship between the kind of meat and the occurrence of *C. perfringens*. A high isolation rate was observed in sausage samples (16/50), followed by luncheon (12/50), while nuggets showed the lowest rate (1/50). The results in Table 2 show that the rate of *C. perfringens* type A was high (24/32), followed by that of type D (7/32), and then the unprecedented isolation of type E in sausage (1/32).

Fig. 1A shows the amplification of alpha toxin gene at 324 bp, representing *C. perfringens* type A, while amplifications of epsilon toxin gene at 655 bp and alpha toxin gene represented *C. perfringens* type D. In addition, Fig. 1A shows the presence of enterotoxigenic *C. perfringens* gene (cpe) at 233 bp. In Fig. 1B, type C was used as a positive control revealing two bands, one at 324 bp for the alpha gene and another at 196 bp for the beta gene. Fig. 1B also shows the amplification of iota toxin gene at 446 bp and alpha toxin gene representing the isolated *C. perfringens* type E. The cpe gene was represented in Fig. 1 by amplification at 233 bp for enterotoxigenic *C. perfringens* type A (Fig. 1A) and *C. perfringens* enterotoxin type E (Fig. 1B). According to Table 3, the enterotoxigenic isolates which carried cpe gene amounted to 9 out of 32 *C. perfringens* isolates with an incidence of 28 %. Enterotoxigenic *C. perfringens* type A was most frequently isolated (6/24), followed by type D (2/7), and then type E (1/1).

**Antibiotic sensitivity test.** The occurrence of antibiotic resistance among 32 *C. perfringens* isolates was as follows: streptomycin (100%), lincomycin (100%), trimethoprim-sulfamethoxazole (94%), ciprofloxacin (41%), cefotaxime (34%), and rifampicin (31%). On the other hand, the isolates showed high sensitivity to amoxicillin (94%) and ampicillin (97%). Out of 32 *C. perfringens* isolates, the nine that harboured the enterotoxin gene, demonstrated a higher resistance to the antibiotics compared to non-enterotoxigenic isolates (Table 4).

* CPE' – *C. perfringens* enterotoxin positive; + CPE' – *C. perfringens* enterotoxin negative
Food can be a source of different human ailments, therefore identification and control of food pathogens are a fundamental part of nourishment microbiology. *C. perfringens* was responsible for food poisoning in the 1940s; ever since, cases of food poisoning due to *C. perfringens* contamination have been reported (6).

According to our results, *C. perfringens* was isolated in 16% of 200 processed chicken meat samples collected from the Egyptian markets. This result is similar to that of Nasr et al. (23) who reported an isolation rate of 14.3%, while in another study, a high 37% prevalence was noted (20). In our study, the occurrence of *C. perfringens* may be possibly attributed to the method adapted in preparing chicken meat products. Moreover, the occurrence of *C. perfringens* may be ascribed to a high protein content in sampled products (13).

As shown in Table 2 and Figs 1A and 1B, *C. perfringens* type A was the most predominant type among *C. perfringens* isolates. The percentages of isolation of that type from luncheon, nuggets, burger, and sausage were 75, 100, 100, and 69, respectively. *C. perfringens* type D was isolated in 25%, 0%, 0%, and 25% of the cases, respectively. *C. perfringens* type E was only isolated from sausage samples, constituting 6% of isolates. These results are in accordance with results of Nasr et al. (23) who found that 70.8% of toxigenic isolates from processed chicken meat products proved to be *C. perfringens* type A, while 12.9% of the isolates belonged to type D.

A small percentage of *C. perfringens* produces the enterotoxin (CPE), which is responsible for food poisoning. CPE has been also associated with sporadic diarrhea and in some cases with sudden infant death syndrome (5).

Table 3 shows that out of 32 *C. perfringens* strains, six of enterotoxigenic strains belonged to type A, two to type D, and one to type E. This is similar to observations of Khan et al. (16) who toxinotyped six *C. perfringens* isolates from raw chicken meat and found that three of them were of type A and one each of the remaining three belonged to types B, C, and D. Likewise, the recognition of enterotoxin genes in type A isolates collected from raw and processed chicken meat products was reported by Guran and Oksuztepe (13). Moreover, the prevalence of *C. perfringens* exotoxin and enterotoxin was not related to the type of product (P > 0.05) (Tables 2 and 3). In fact, *C. perfringens* type A was isolated in almost all studies in which poultry meat was examined (24). Additionally, cpe gene was identified in *C. perfringens* isolates of all types (A-E), but type A was unusually common (18).

Interestingly, our results (Fig. 1B) provided some novel information about the isolation of *C. perfringens* enterotoxin type E from chicken sausage. This observation may account for several foodborne *C. perfringens* outbreaks that could be linked mainly to chromosomal cpe type A strains with heat-resistant spores, or occasionally heat-resistant spore-forming plasmid cpe type A strains; both can be found in retail foods (21).

Furthermore, we examined the occurrence of resistance of 32 *C. perfringens* isolates to eight antibiotics which are widely used in poultry farms (Table 4). It was found that antibiotic sensitivity was highly related to the type of antibiotic used, either in *C. perfringens* enterotoxin-positive or -negative strains. The resistance to streptomycin, lincomycin, and trimethoprim-sulfamethoxazole was 100%, 100%, and 94% respectively, while appropriate percentages for ciprofloxacin, cefotaxime, and rifampicin were 41, 34, and 31, respectively. On the other hand, *C. perfringens* isolates showed high sensitivity to amoxicillin (94%) and ampicillin (97%).

**Discussion**

Food can be a source of different human ailments, therefore identification and control of food pathogens are a fundamental part of nourishment microbiology. *C. perfringens* was responsible for food poisoning in the 1940s; ever since, cases of food poisoning due to *C. perfringens* contamination have been reported (6).

According to our results, *C. perfringens* was isolated in 16% of 200 processed chicken meat samples collected from the Egyptian markets. This result is similar to that of Nasr et al. (23) who reported an isolation rate of 14.3%, while in another study, a high 37% prevalence was noted (20). In our study, the occurrence of *C. perfringens* may be possibly attributed to the method adapted in preparing chicken meat products. Moreover, the occurrence of *C. perfringens* isolates showed high sensitivity to amoxicillin (94%) and ampicillin (97%).

**Fig. 1.** Agarose gel electrophoresis of multiplex PCR products of *C. perfringens* strains isolated from selected chicken meat products and a positive control

A) Lane 1 – 50bp DNA ladder. Lane 2 – *C. perfringens* type D (positive control). Lane 6 – *C. perfringens* type A, enterotoxin. Lanes 3, 4, 5, and 7 to 12 – *C. perfringens* type A

B) Lane 1 – 50bp DNA ladder. Lane 2 – *C. perfringens* type C (positive control). Lane 3 – *C. perfringens* type D. Lane 6 – *C. perfringens* type E, enterotoxin. Lanes 4, 5, and 7 to 12 – *C. perfringens* type A
These results are in agreement with those of Osman and Elhariri (26) who mentioned that *C. perfringens* isolates showed high resistance to streptomycin (100%), lincomycin (100%), and trimethoprim-sulfamethoxazole (98%). Furthermore, previously reported results (27, 2) showed intermediate sensitivity of *C. perfringens* to cefotaxime, ciprofloxacin, and low sensitivity to lincomycin. Abd-El Gwad and Abd El-Kader (1) demonstrated that *C. perfringens* isolates were highly sensitive to ampicillin, ciprofloxacin, and amoxicillin, which is consistent with our results suggesting that ampicillin and amoxicillin may be the drugs of choice for *C. perfringens* infection (3). Moreover, we found that *C. perfringens* isolates which carried enterotoxin gene showed a higher resistance to the antibiotics than non-enterotoxigenic isolates.

The frequent isolation of *C. perfringens* from processed chicken meat makes a public health risk. Its prevalence may be due to unhygienic measures not only during chicken rearing, but also during industrial processing. *C. perfringens* in poultry seems to occur very early and can be transmitted within the broiler chicken production, starting from the hatchery (10). Notably, *C. perfringens* is found in eggshell cracks, chicken fluff, and paper pads present in the hatchery (11).

Our study affirmed that there is a noticeable increase in the occurrence of enterotoxigenic *C. perfringens* in processed chicken meat, especially sausage. Moreover, we identified *C. perfringens* enterotoxin type E in chicken meat. The study also contends that enterotoxigenic isolates of *C. perfringens* are more resistant to antibiotics than non-enterotoxigenic isolates.
